Results reported thus far confirm the benefits of merging direct and indirect strategies in the pursuit of preventive goals. Summarizing findings from the Elmira and Memphis samples, Olds et al. (1998) report that compared to mothers randomly assigned to the control condition, those assigned to the Home Visitation intervention smoked less and improved their diets during pregnancy, had fewer hypertensive disorders and preterm deliveries. Postnatal differences favoring the intervention group included fewer health care encounters for the infants relating to injuries and ingestions and, in the Elmira sample, lower rates of child abuse and neglect. These results suggests that intended improvements in maternal caregiving were achieved. During the four-year period following program participation, Home Visited mothers had fewer pregnancies; more program mothers completed their education, became employed, and independent of welfare than control mothers. Cost-effectiveness analyses confirm the long-term economic benefits of this program; program costs are recovered within a few years and continue to accrue over the life of the mother and her offspring. These investigators acknowledge that the nature and extent of program effects vary across individual (Olds & Korfmacher, 1998b), familial (Cole, Kitzman, Olds, & Sidaro, 1998), and program process (Korfmacher, Kitzman, & Olds, 1998) characteristics.

It is important to note that similarly broad and significant effects have not been reported for approaches to home visitation (Olds & Kitzman, 1993). Olds (personal communication, April, 1998) supports my impression that what differentiates his approach from its counterparts is not only reliance on licensed nurses as the providers (the Denver replication specifically examines the differential impact of nurse and paraprofessional provider) but its clear intent to produce lasting changes in the mother. In effect, an essential component of the Home Visitation program is for the visitor to make herself unnecessary, that is, to achieve the consultant's goal of putting oneself out of business. Echoing the commitment of the Child Guidance Movement (Mannino & Shore, 1986), the program enabled the mothers both to solve immediate problems and to anticipate and thereby avoid or solve future problems. My impression is that Olds' approach empowers the mothers and embodies the principle reflected in the adage "give me a fish and I eat for a day. Teach me to fish and I eat for a lifetime."

6.13.10 FINAL COMMENT

The position presented in this chapter is that significant health and mental health goals can be achieved through the development, evaluation, and dissemination of theory-based, scientifically validated, and politically and economically supported preventive interventions delivered through the application of indirect/consultation strategies. A review of the history of human service strategies over the past century and particularly since passage of the Community Mental Health Centers Act documents repeated attempt to pursue this goal. Good intentions and sincere commitment, however, have not been sufficient to place this effort into the fabric of the human and social service network. For that to occur, I am arguing, requires a combination of theoretical justification, flexibility in professional attitudes and roles, and viable examples of effective applications. All of those conditions appear to be presently available! Ideally, this chapter will contribute in some small way to the discipline's recognition and seizure of this opportunity.

6.14.1 INTRODUCTION

Images are defined as contents of consciousness that possess sensory qualities, as opposed to those which are purely verbal or abstract. This definition embraces dreams and waking images of various kinds. Whilst images can have qualities associated with any of the sensory modalities, it seems that visual imagery is the most common (Horowitz, 1970). Memories, too, can come to awareness as mental contents with sensory qualities, most vividly in the case of "flash bulb" memories, and also in intrusive memories and reliving experiences following trauma. Memories themselves are not reexcitations of fixed traces, but are imaginative reconstructions (Bartlett, 1932) that can be altered or even partly created by varying retrieval procedures (Loftus & Palmer, 1974). These observations give weight to the idea that some memories are in fact more like imaginative images, although these may be as vivid and convincing as "real" memories. However, this distinction may be a difficult one to make, since it is also true (as discussed later in this chapter) that imaginative images themselves contain much input from memory, even though the person having the image may not be aware of the connections with their past.

Among the contents of consciousness are verbal thoughts and images in various modalities, some of which are considered to be memories. One might wonder why one would choose to work on imagery rather than purely verbal thought. Two possible reasons are that images condense a great deal of information, and they reveal layers of meaning which are idiosyncratic. It has also been suggested (e.g., Paivio, 1986; Singer, 1974) that imagery via sensory modalities is one of several major coding systems the brain has for organizing and storing experience, and that images are likely to afford greater emotional arousal than the verbal encoding system. Buzan and Buzan (1997) suggest that images are often more evocative than words, and are more precise and potent in triggering a wide range of associations. Thus, changing or transforming an image might be hypothesized to be more likely to bring about a significant emotional shift than challenging a verbal thought.

When dramatic, life altering events occur people tend to remember a great deal of detail about the circumstances in which the event occurred. Such memories are called "flashbulb memories," and it almost appears as if the mind takes a kind of photograph of the situation at such times. An example would be the way in which everyone can remember where they were when the death of John F. Kennedy occurred (Ornstein, 1992). Work in post-traumatic stress disorder (PTSD; Ehlers, 1997) suggests that during traumatic incidents processing may be data-driven rather than semantic and memories may be in a fragmented, sensory form, with associated high affect when they are recalled. Such memories are often deliberately avoided by the client, although they reappear as intrusive memories, nightmares, and spontaneous experiences of reliving. Brewin, Dalgleish, and Joseph (1996) have suggested that there are two types of memory, namely verbally accessible memories and situationally accessible memories (SAMS). The latter are not verbally accessible, but may be triggered by sensory environmental cues or emotions which match those present during the trauma. Several other writers have suggested that there may be a number of different representation systems that are involved in the processing of information (cf the Interacting Cognitive Subsytems approach, Barnard & Teasdale, 1991; and the SPAARS model, Power & Dalgleish, 1997).

Following resolution of trauma, memories seem to be stored in a more orderly, narrative form which is less fragmented (Foa, Molnar, & Cashman, 1995) and they are less likely to be upsetting to recall, or to be evoked involuntarily by sensory cues. Such observations support the idea that there may be several ways of encoding material, and there may be a place in therapy for bringing more fragmented imaginal material into awareness in order to integrate it with other material available in a verbal store. There are parallels here with what have been referred to as primary and secondary process thinking (Freud, 1962).

There are other properties of images which affect their usefulness in therapy. They may occur spontaneously, but they can also be deliberately evoked, transformed, or suppressed. They can reflect perspectives on the past, the present, or the future, and can be literal or symbolic. They can appear to be veridical memories, or at the other end of the scale they can be seen as imaginative images. However, their content is neccessarily determined by experience.

6.14.2 AN OVERVIEW OF THE USE OF IMAGERY IN THERAPY

In the history of psychology "mental contents" have at times been seen an appropriate area of study (e.g., by the early introspectionists, such as William James, Galton, and Titchener), and at times relegated to the essentially unknowable "black box" (e.g., by Skinner and Watson). Indeed, Brown (1958) expressed a prevailing attitude by writing that "In 1913 John Watson mercifully closed the bloodshot inner eye of American psychology. With great relief the profession trained its exteroceptors on the laboratory animal." However, early in the history of behavior therapy imaginal material crept back into the arena, and was used instead of *in vivo* material, for example, in various forms of exposure therapy, such as Wolpe's desensitization (Wolpe, 1958) or Stampfl's implosion therapy (Stampfl & Levis, 1967) and imaginal flooding (e.g., Foa, Skeketee, & Grayson, 1985). Images have also been used in other behavioral treatments, such as various types of covert conditioning (Cautela, 1977). Wolpe (1958) legitimized the use of covert processes within a behavioral framework through the assumption that if someone is led to imagine particular events this can lead to predictable changes in behavior. Jacobsen (1942) had also paved the way for this work, by demonstrating that simply imagining a situation like running produced responses in the body such as those produced by real running. It had also been shown that imagining a feared situation produced evidence of the "fight or flight" reflex, with changes, for example, in the galvanic skin response (GSR). In behavior therapy, images have been used to provide attenuated forms of both stimuli and responses.

Despite the use of imaginal material the main therapeutic techniques used in behavior therapy were thought to have been derived from learning theory, and to involve classical and operant conditioning, deconditioning, and extinction. The cognitive therapies took a fresh approach by emphasizing the fact that between stimulus and response there appear to be appraisals, which can be worked on directly, with profound effects on behavior and emotion. These appraisals include "meanings, significances, and imagery" (Beck, 1970), and we are advised that in cognitive therapy we should attend to thoughts and images (Beck, Laude, & Bonhert, 1974; Ottaviani & Beck, 1987). More specifically, Beck (1976) held that meanings were the things we needed to change, and that these are accessible through thoughts and images. The picture is further complicated by the fact that not all appraisals are necessarily in full awareness or reported spontaneously, although they are potentially accessible to consciousness.

Also within a cognitive therapy framework, Freeman (1981) and Freeman and Boyll (1992) discuss the way in which the images in dreams and fantasies provide access to the individual's idiosyncratic interpretations of reality, and distortions therein. This is also true where visual imagery accompanies strong emotion, and such images can form a basis for the reexamination and restructuring of beliefs.

In an interesting paper on the use of Gestalt techniques in cognitive therapy, Edwards (1989) briefly reviews the use of directed visualization techniques in Tibetan Buddhism, Jung's active imagination (Watkins, 1976), Assagioli's (1965) guided fantasy in psychosynthesis, Leuner's (1984) guided affective imagery, and the imagery psychodrama of Perls and other Gestalt therapists (Perls, 1971; Stevens, 1971). He also describes its application to the treatment of depression (Shultz, 1984) and phobias (Habeck & Sheik, 1984), and in controlling pain (Bresler, 1984) and increasing resistance to cancer (Hall, 1984). Much fuller reviews of many imagery techniques and their theoretical backgrounds have been given by Singer (1974) and Samuels and Samuels (1975). It is beyond the scope of this chapter to review all previous attempts to treat physical and psychological disorders using imagery techniques, so the main focus will be on the major work done in this area by clinical psychologists, working in the cognitive-behavioral framework, with the stance of the scientist practitioner. However, as Edwards points out, work in different theoretical frameworks is still worth studying, since despite its dissimilar surface characteristics the cognitive restructuring that takes place through guided imagery has close affinity to that which takes place through guided discovery in cognitive therapy, and techniques such as those used by Gestalt therapists, for example, can offer useful methods of identifying key cognitions (Arnkoff, 1981).

For this reason it may be useful to consider some of the earlier uses of visualization in psychiatry and clinical psychology. The first clinician credited with eliciting images to treat patients was Breuer (see Freud & Breuer, 1955). In 1881, when Freud was his student, he treated Anna O. by hypnotizing her, and encouraging her to produce what he called fancies, or daydreams. Freud describes the way in which her symptoms of hysterical paralysis would disappear, when in hypnosis she was made to remember the situation and associative connections under which they first appeared, provided free expression was given to the emotions these evoked. Later Freud applied similar techniques, but he abandoned the use of hypnosis when he realized that patients who could not be hypnotized could still produce similar types of early traumatic memory images and affect. Initially these occurred in response to the suggestion that a memory would come to mind when Freud put his hand on the patient's head, but this was later altered to an emphasis on free association and the analysis of dreams and symptomatic acts. Freud considered images to be part of primary process thinking, more primitive than ordinary thinking, developed earlier in childhood, and more direct, immediate, and less restrained by logic. He also felt that memory images were often not lost to the person, but stored in the unconscious.

In hypnosis, both imaginative and memory images may be elicited, again whilst the patient is in a deeply relaxed state. Age regression techniques are used to evoke memory images, from earlier in the patient's life, or even in some cases from supposed past lives. These can be extremely vivid and realistic, and this capacity of people in relaxed states to be able to virtually relive certain experiences has been noted by many therapists. Grof (1976) has described such experiences in his patients who explored altered states of consciousness under the effects of LSD, or during holotropic breathwork sessions, following hyperventilation and listening to music whilst physically relaxed. Where memory images are evoked using such methods they may encompass sensory material in any or all modalities, and associated affects. The same is true with images that can be recognized as imaginative images, leaving a gray area where it is impossible to say to what extent a veridical memory has been evoked, and thus making it important to consider the idea that some memories may be "false" ones, a problem which Freud himself encountered.

In the section on working with images in cognitive therapy some attention will be paid to the restructuring of memories, a topic which also has relevance in the treatment of PTSD, where treatments based on the repeated reliving of traumatic memories seem to hold the most promise (e.g., Foa, Rothbaum, Riggs, & Murdock, 1991). Edwards (1990) has written a masterly review of work on early traumatic memories in various theoretical frameworks, including the Freudian approach. Freud was initially very interested in early memories, but later moved away from his work on this topic, partly because he came to believe that some of the memories reported were in fact fantasies or imaginative images, and partly because in any case he believed that simply uncovering and analyzing traumatic memories would only be useful if accompanied by a wish to use these discoveries as a basis for changing things in the present. This second notion would be agreeable to cognitive therapists working in the 1990s. Bowlby (1985) criticised analysts for steering away from work on early memories, recognizing that recovery of a traumatic memory can allow distorted schemas to be recognized and restructured. Arieti (1985) reformulated the Freudian approach, and based his new approach on a cognitive developmental model. The techniques in use in the 1990s in cognitive therapy will be described below.

Jung gave great importance to the use of symbolic or imaginative images in therapy. He believed that images are often archetypal in nature, and that there is a universal language of symbols, common across different cultures and periods of history. Jung wrote that he attempted to translate emotions into images, to find the images which were concealed in the emotions. He felt that if emotion-laden images were left in the unconscious they could give rise to neurotic symptoms, but the more they could be brought into consciousness the calmer the person would become. Jung developed a technique called active imagination, during which the person is asked to meditate, remaining free of any goal. They then invite images to appear, and watch them without intervening. It is also possible to talk to the images, or to question them. Subsequently these visualizations are discussed with the therapist. This technique is more likely to evoke imaginative rather than memory images. Many of the images symbolize aspects of personal growth. Jung felt that simply bringing images to awareness and reflecting on them could be therapeutic, as Freud originally believed would be the case with memory images.

Imaginative images have been used in a variety of other therapies. Many of these have been more directive in their approach than Jung. The content of the image may be specified to some extent, and suggestions made for ways in which the image may be manipulated or controlled. An example would be Leuner's Guided Affective Imagery (Leuner, 1969). The therapist suggests a theme that the patient then works with. They may be asked to visualize a scene such as a mountain, a meadow, a house, or a stream, or they may evoke an image of a relative, a sexual partner, or someone of their own sex. Within the imaginary scene they could be prompted to make a journey, and then deal with the symbolic material which appears. This may involve confrontation, reconciliation, or other ways of dealing with what comes up in the imagery. The theory behind the technique is that the material elicited will symbolize important areas of conflict in the person's life. Once again the imaginary material is evoked following a period of relaxation in a darkened room.

Assagioli (1965) has used symbolic visualization as part of the therapy in psychosynthesis. The patient closes their eyes and relaxes, and is then asked to dwell on symbols of integration and balance, of harmony in relationships, of the masculine and the feminine, and of affective states. Focusing on particular symbols in this way is supposed to bring about increased control in the inner and outer life. Sometimes it is suggested that the patient should transform the image, so that, for example, a seed becomes a tree, or a worm becomes a butterfly.

Other therapists have emphasized the importance of interacting with the elements of the imaginative image. For example, Gestalt therapists (Perls, 1971; Stevens 1971), working with an image or daydream of an imaginary scene, would suggest to the patient that they imagine themselves as each of the other characters in the image, and even as an animal, or an inanimate object, such as the stick which is beating a dog. In this way different perspectives are developed which may be useful in therapy.

Before the sections on working with images in behavioral and cognitive therapies a brief outline of phenomenology in the realm of imagery is provided. This is biased towards a study of imagery in neurotic disorders, but is worth noting that a great deal of work has been done on imagery in other fields, notably in physical medicine and in sports psychology.

6.14.3 TYPES OF IMAGES IN PSYCHOLOGICAL DISORDERS

The literature suggests that images abound in psychological states, perhaps particularly in anxiety disorders. Ottaviani and Beck (1987) revealed that images are common in people with panic disorder, and frequent themes are those of physical and mental catastrophe, as is typical of their anxious thoughts. Beck et al. (1974) looked at ideational components in anxiety neurosis, and found themes to do with danger, both physical and psychosocial, in the thoughts and images collected.

Images in phobias have been studied by several authors. Watts, Sharrock, and Trezise (1986) hypothesized that phobics would have imagery connected with their phobias that was relatively lacking in detail and elaboration. They discovered in a study of visual imagery of coping with a spider that the accounts of phobics were briefer and less elaborated, suggesting a lack of coping imagery. However, in another study of stimulus imagery immediately following exposure, phobic subjects reported being more aware of the image, but did not report less detail (as predicted). This was surprising in view of a previous study by Watts, Trezise, and Sharrock (1986) in which poor recognition memory for phobic stimuli was demonstrated and taken as evidence for poorly elaborated stimulus processing.

Beck (1976) reported on his studies of the content of dreams and other ideational material in people suffering with depression. These dreams reflect themes of defeat, defectiveness, thwarting, and deprivation, rather than the themes predicted by psychoanalysis, to do with hostility turned inwards. It was this work, an unsuccessful attempt to provide empirical support for psychodynamic views on depression, which led to the development of the cognitive model of depression. There are several studies on the themes in depressive dreams (Beck & Hurvich, 1959; Beck & Ward, 1961), but less has been written about depressive images. Layden (personal communication) also suggests that depression is characterized by a lack of positive images, particularly of the future, which might, if they existed, have the power to motivate the depressed individual to work towards realizing this hoped for vision.

De Silva (1986) has studied images in obsessive-compulsive disorder. He found, like the authors above, that in general the images were not different in content from other obsessional cognitions. The most common themes were those of death and decay, illness and injury, violence and disaster, and sex and blasphemy. He distinguishes between four different types of image: (i) obsessional ones, which are unwanted and intrusive; (ii) compulsive images, which are formed deliberately to neutralize an obsessional image, (which can be corrective versions of the original, or independent images bearing no relation to the obsessional one they are meant to neutralize); (iii) disaster images, of what might happen if the obsessions are not acted upon; and (iv) disruptive images, which can interrupt compulsive rituals, and make it seem imperative to start them again. The most interesting distinction here is probably the observation that images have different functions, some constituting obsessions (i.e., unwanted, intrusive images), and some being covert compulsions or rituals (i.e., images which are deliberately formed; see also Salkovskis & Westbrook, 1989). This highlights the observation that some images are seen as threatening or likely to lead to harmful consequences, whilst some are seen as capable of warding off harm.

Wells and Hackmann (1993) looked at images in health anxiety, and found that they contained a wealth of information. As with automatic thoughts (Warwick & Salkovskis, 1990) the themes expressed were those of misinterpretation of bodily sensations and symptoms, and overestimation of the likelihood of illness or death. However, the images also began to answer the question of what is so particularly bad about such calamities for people with health anxiety. For many the real calamity lay in the interpersonal consequences of illness or death (see Section 6.14.5). Like obsessional patients these individuals also had many superstitious or metaphysical beliefs, often involving fears that thinking in a particular way, or having certain images, could affect the future, or tempt providence. For example, some individuals fear that imagining death or illness could make it happen, or thinking of how lucky they are to be well, or picturing a happy future, could invite disaster. Sometimes the belief is like the popular view that negative thinking is bad for the immune system, but more frequently the mechanism is thought to be God or Fate. These ideas lead to attempts to control or neutralise images, in ways which may well exacerbate the problem, since suppressing thoughts and images often leads to an increase in intrusions.

In generalized anxiety disorder patients complain about worrying. Worry has been defined as consisting of long chains of negative thought that are predominantly verbal in form, and aimed at problem solving (Borkovec, Robinson, Pruzinsky, & DePree, 1983). Borkovec and Inz (1990) have suggested that the predominantly verbal activity of worrying diverts attention away from imaginal activity which is more closely linked to the activation of physiological arousal. Furthermore, they also suggest this may block exposure to it and lead to symptoms of failed emotional processing, including more intrusions of imaginal material. Where there is imaginal material typical themes are of psychosocial or physical danger (see Beck et al., 1974).

Wells, Ahmed, and Clark (1995) have also studied images in social phobics. Here, the finding was that the images of social phobics when deliberately generated depicted the self, seen in a distorted way, and as if seen from an external perspective. Thus, a social phobic tends to see themself as they imagine others might, with a bright red or sweaty face, or with shaking hands or a childish appearance. This also happens in spontaneous images social phobics get in naturalistic situations (Hackmann, Surawy, & Clark, 1998). Here the images are usually visual ones, but are sometimes sensory impressions rather than visual images. However, they are still perceived from an external view-point, in contrast with the images less socially anxious people get when anxious in a social situation. These images are often recurrent, and depict the individual in an embarrassing or humiliating predicament, with some awareness of an audience. When asked when in their lives they first remember feeling that way a specific incident is often recalled, in which they were criticised or bullied (Hackmann & Clark, in press). Images in social phobia have an important part to play in maintaining the disorder, in that like the images in other disorders they tend to be regarded as reflecting reality, and therefore they are often acted upon, giving rise to avoidant behaviours. They also form part of the postmortem, in which a negative, ruminative going over of past imagined and predicted future failures leads to a set of exaggerated and distorted images and memories and images, with a consequent enhancement of anxiety (Clark & Wells, 1995).

Agoraphobics often have recurrent images (Hackmann & Surawy, in press). In these the patients image themselves from an external viewpoint, experiencing the sort of physical or mental calamities feared by panic disorder patients. However, in their images they also see an interpersonal context in which the events are occurring. Typically they are either ignored and experience themselves as far from home or help, or they attract unwelcome attention, which is embarrassing, and may also have the effect of making it harder for them to reach the safety of home. For example, someone might picture themself being taken to hospital and kept there against their will, whist another might see themself lost and alone in an unreal world, where it has become impossible to reach home.

In therapy with patients suffering from a variety of anxiety disorders it has been noted that there is often close similarity between the sensory and interpersonal content of recurrent images and upsetting childhood memories (Hackmann, 1995; Hackmann & Clark, in press; Hackmann & Surawy, in press; Wells & Hackmann, 1993). It has also been reported that in depression individuals often have intrusive memories, linked to their current mood, of childhood traumas (Brewin, Hunter, Carroll, & Tata, 1996; Kuyken & Brewin, 1994; Spenceley & Jerrom, 1997). This suggests that some images may have more than a passing resemblance to reliving experiences in PTSD.

Images in PTSD tend to appear like flashbacks, often to scenes which have been especially traumatic. Some of them are so vivid that it is as if the patient is reliving the trauma, in rich sensory detail, as if it were happening again. Often the intrusions people get spontaneously are always of the same fragment (or fragments) of memory. One patient always saw the headlights of a car approaching her head-on, on the wrong side of the road. It was the headlights which she always saw when waking up in terror in the night, or when lying on the sofa and looking at the corner into which she had gazed as she spent weeks lying down, recovering from the accident. Often it appears that the fragments which intrude are those which have not been resolved in the mind of the patient. For example, the patient who described the headlights on the wrong side of the road linked to the idea that she might have been able to prevent the accident. Revisiting the scene of the accident helped her to realize that there was nothing she could have done, upon which the intrusions decreased markedly. Nightmares in PTSD often involve a total and accurate replay of the traumatic events. For example, someone who was attacked whilst recovering from surgery repeatedly dreamed that she saw the hands of the hospital clock pointing to 10 minutes to three, then experienced the attack again, and woke at exactly three a.m., the time at which the attack ended and she was safe again.

As mentioned above, images in PTSD can involve any of the senses. The first patient described above was able to actually hear the crunch of metal, smell the petrol and taste it, see the steam rising, and feel the actual impact. Imagining the crash gave her pain in her chest and neck, which had been hurt in the crash a year before. Sometimes these flashbacks are not completely veridical memories. For example, the same patient had been told that since the man who crashed into her was foreign he could not be prevented from coming back in the future and hiring another car. At one point this was represented in an image of him crashing into her again in the future, and walking up to talk to her in a way that had not happened in the real accident. She took this to mean that this was what would really happen in the future. Similar features are noted after sexual abuse—there is reliving, not only in the visual modality, but also of sounds, tastes, smells, and sensations, and there can be mixture of images and memories. There is also often fear in both disorders that letting these mental contents into full awareness could have serious mental or physical consequences. Once again this leads to attempts to suppress such intrusions, which can then perpetuate the problem.

6.14.4 WORKING WITH IMAGES IN BEHAVIOR THERAPY

6.14.4.1 Desensitization

In 1958, Wolpe published his famous book about desensitization. This was based on experiments on the counter-conditioning of fear responses in laboratory animals through the pairing of stimuli which had been paired previously with noxious stimuli with positive stimuli (e.g., Masserman's experiments with cats). Wolpe called the process "reciprocal inhibition," and paired the feared stimuli with relaxation, or with eating, or sexual stimuli. This process, when repeated a number of times, appeared to decrease the amount of fear evoked by the negative stimulus, and increase the amount of approach behavior. The feared stimuli were approached in a graded way, via a carefully arranged hierarchy of feared situations. Wolpe discovered that imaginal presentation of stimuli was easier to organize than *in vivo* presentation, and also that the most practical activity to pair with the stimulus was relaxation. Results with this method were very impressive, and in 1977 Smith and Glass concluded that desensitization-type behavior therapies produced larger average therapeutic effects than any other type of psychotherapy, at that time, particularly in the treatment of phobias.

Yet the important ingredients in the procedure remain uncertain. The use of a systematic hierarchy and progressive relaxation of the muscles have been shown not to be essential (Dawson & McMurray, 1978). Wilkins (1971) found that the research literature seemed to indicate that the significant ingredient of systematic desensitization and similar treatments is the use of imagery by the client. Weitzman (1967) interviewed patients after every session of desensitization. He found that during the period of silence in which the client held the image the experience was not a static one. Other images and associations tended to occur, and the image at the end of the period had often undergone some changes. Also, those who observed Wolpe conducting the therapy underscored the process of cognitive exploration and discussion which occurred. The relationship of this approach to learning theory has been questioned, by Breger and McGaugh (1965). Singer and Pope (1978) conclude that therapy seems to work by changing the client's anticipations, self-communications, and images with respect to the feared situations. The mechanism remains to be fully investigated.

6.14.4.2 Covert Conditioning

Cautela (1977) produced a useful review of the assumptions and procedures in covert conditioning, in which it was conceptualized in operant-conditioning terms. The main assumption was that behavior patterns could be strengthened or weakened by imagining them to be followed by either positive or negative reinforcement, or by punishment, or by an absence of the previous reinforcers. This was not the original way in which covert sensitization was conceptualized (Cautela, 1967), when it was seen more as a classical conditioning procedure, in which the objective to was the opposite from that of desensitization, in that the aim was to render a previously positive stimulus noxious, by pairing it with imaginal stimuli which are aversive, and thus decrease the chance that presenting the original stimulus will lead to undesired behaviors. By 1977 the procedure was considered to work best if the maladaptive behavior was imagined after the triggering stimulus, and then followed by negative consequences. Self-control or relief scenes were also added, and alternated with aversive scenes. A relief scene might involve having the temptation to carry out an undesirable behavior, but starting to feel ill, then deciding to resist the temptation, and then feeling immediately better, and proud to have resisted it.

The most extensive use of such techniques has been by Cautela, and in a series of papers he has reported its use in the treatment of many maladaptive approach behaviors, such as smoking, drinking, obesity, compulsive stealing, and deviant sexual behaviors (Cautela, 1966, 1967, 1971). Cautela has developed a set of graphic and disgusting images, which can be used as they are, or elaborated with the patient. These are paired with mental images of the desired stimulus or maladaptive behavior. For example, a patient might be asked to imagine a desired sexual partner in a disgustingly filthy cellar, which causes the patient to vomit (in imagination) all over himself and the desirable partner. The disgusting scene is terminated by his escape from the cellar, and the other individual. It is interesting to note that in many studies of covert sensitization progressive relaxation is used, not for the purpose of reciprocal inhibition, but to enhance the generation of vigorous imagery, or stronger emotional reactions. Covert response cost has also been described by Cautela (1970a). In this case the removal of an imagined positive reinforcer is contingent on a real or (more usually) imagined response, which can be either a maladaptive approach or avoidance response. This technique is relatively untested.

Covert positive reinforcement has also been used by Cautela (1970b). In this procedure the person rewards himself in imagination for the desired behavior in real life or in imagination. Covert-positive reinforcement can be used to reinforce both approach and avoidance behaviors. It is considered to be an operant procedure in which a covert reinforcer is used to increase probability. It need not involve relaxation or hierarchical presentation of material, so it differs in a number of respects from desensitization.

Cautela also describes a process he calls covert extinction, in which the client is asked to imagine himself carrying out the behavior he wishes to curtail, without it bringing any of the usual satisfactions. For example, a smoker might imagine himself smoking without being able to taste or smell the cigarette, and without any decrease in his level of stress. Cautela (1971) reports a few studies where these techniques were used successfully, and also warns of several aspects of treatment which the therapist and patient need to be aware of. Finally, Cautela describes covert modeling, in which the learning or alteration of new behaviors is effected by imagining others carrying out the behavior, and observing the imagined consequences. A shaping process can also be used, where the patient first imagines observing someone else carry out the behavior, then watches themself do it, then imagines actually doing it, and finally carries it out. There is experimental evidence to support the idea that this is a useful technique (Cautela, 1977; Kazdin 1974).

6.14.4.3 Implosion and Imaginal Flooding

This technique attracted considerable attention in the 1960s, following a theoretical paper by Stampfl and Levis (1967). Stampfl viewed the defense mechanisms of the neurotic as avoidance responses which had been learned and perpetuated because they reduced anxiety. Originally the patient, often when very young, has traumatic experiences, in which they has been rejected, humiliated, deprived, or punished. Subsequently everything associated with these events, such as the sights, sounds, and smells, elicit anxiety, and these cues motivate behavior. This behavior can be considered defensive if it reduces anxiety, and is consequently reinforced.

Stampfl theorized that these neurotic defensive behaviors could be unlearned if something very similar to the original trauma could be strongly recreated, in the absence of any real punishment, deprivation, and so on. The use of imaginal material proved a convenient vehicle for this, as the patient was often able to evoke the visual cues, and the therapist could provide suitable sound effects. It was hypothesized that this process of play-acting the fears, and reliving the trauma could lead to the extinction of anxiety. Thus, the theory spanned psychoanalytic and learning theory ideas about anxiety.

The first research study was by Hogan (1966). In it psychotics were given either implosive or more traditional psychotherapy. There was a significant difference between the two groups, with more of the implosive therapy patients being discharged after one year. Levis and Carrera (1967) reported on the effects of 10 hours of implosive therapy in neurotic patients, with a significant difference in two of the 16 MMPI scales compared with control groups. In a second study, Hogan and Kirchner (1967) studied rat phobics. Those in the implosive group were significantly more likely to pick up a rat in the behavior test than those who had been given only pleasant imagery. Hogan and Kirchner (1968) also reported a successful one-session intervention with snake phobics. In another study, Kirchner and Hogan (1966) administered the implosive therapy standardized tape simultaneously to a group of rat phobics in a single session, and played music on a standardized tape to the control group. The implosive group were superior to the control group in their willingness to pick up a rat. It is interesting that these results were obtained with such standardized material, in view of the original theory behind implosion, which aimed to extinguish the anxiety reaction to highly idiosyncratic sensory cues present at the time of the supposed original trauma. This suggests that the psychodynamic aspects of the theory may be redundant.

However, it is also worth noting that Levis (1980) remarks that one of the most interesting phenomena to occur with the use of implosion therapy is the apparent reactivation or redintegration of early memories during or following the presentation of imaginal scenes depicting the most feared outcomes possible in an individual's feared situations. The emergence of this new material helps shape the course of new imaginal sessions, and is thought to provide a closer approximation of the avoided conditioned stimulus complex from which one is attempting to extinguish anxiety. Several examples are provided in this chapter of the reemergence of traumatic early memories during therapy, and an example of the same phenomenon is described with reference to implosion therapy for a recuurent nightmare.

In the 1970s there were several studies comparing imaginal flooding with other behavioral treatments. For fearful volunteers and simple phobics *in vivo* exposure treatment generated better results than imaginal procedures (Bandura, Blanchard, & Ritter, 1969; Barlow, Leitenberg, Agras, & Wincze, 1969; Dyckman & Cowan, 1978; Mathews, 1978; Sherman, 1972). With obsessive compulsives both media produce similar outcomes (Foa et al., 1985; Rabavilas, Boulougouris, & Stelanis, 1976). With agoraphobics two studies indicate the superiority of *in vivo* exposure (Emmelkamp & Wessells, 1975; Stern & Marks, 1973) and two studies indicate equivalent gains (Chambless & Goldstein, 1982; Mathews et al., 1976).

Foa, Steketee, Turner, and Fischer (1980) looked more closely at this with a group of obsessive compulsives with checking rituals. In addition to their feared situations which they were exposed to *in vivo*, they also had disaster fears for the future which could only be presented in imagination. Half the subjects received two hours of *in vivo* exposure only. The other half received only half an hour of exposure, with 90 minutes of imaginal exposure to the feared disasters. Both groups improved significantly, to the same degree. However, the group that received the combined treatment retained their gains, whilst some relapse was evident in the *in vivo* only group, suggesting that more of the elements of the fear structures (Foa & Kozac, 1986) were addressed in the imaginal exposure than in the *in vivo* exposure group, leading to more successful emotional processing.

6.14.4.4 Reliving Treatment in Post-traumatic Stress Disorder

A technique which has proved relatively successful in the treatment of PTSD is that of repeated imaginal reliving of the trauma (Foa et al, 1991). After preparation and socialization as to the treatment rationale clients are asked to repeatedly relive their traumatic experiences, describing them aloud, in the first person, and attempting to reexperience exactly what happened to them. Particular attention is paid to the hot spots, that is, the most emotionally laden parts of the memory. Clients are asked to take home tape-recordings of these sessions, and listen to them daily if possible. This procedure frequently results in a decrease in the associated affect, particularly the emotion of fear. It also results in the accounts becoming less fragmented, more organized (i.e., indicating more attempts to understand the traumatic events), more complete, longer, and richer in thoughts and emotions, but with less detail about the events themselves (Foa et al., 1995). Overall this procedure also produces good symptomatic relief in real life. Also, there was greatest change in indices of fragmentation and organization in the narratives of those who improved the most.

These results are in line with Foa's theoretical position, that PTSD may occur in cases where there has been inadequate emotional processing, possibly because the terrible memories have somehow been held out of awareness (Foa & Kozac, 1986). Jaycox and Foa (1996) discuss possible obstacles in implementing exposure therapy in certain cases of PTSD. These include extreme anger, emotional numbing, and overwhelming anxiety. Practical suggestions are made, such as projecting the imagery on to an imaginary wall, and "zooming out" from the images if the distress of the client becomes extreme, to the point where the sense of current reality is about to be lost.

It remains to be seen whether the results of reliving treatment can be improved upon by giving the intervention a more complex rationale, and tackling some of the issues raised by using techniques such as those derived from cognitive therapy to challenge distorted ideas about the trauma itself, or its psychological sequelae.

6.14.4.5 Eye Movement Desensitization and Reliving

Shapiro (1989) published details of a new treatment for PTSD, which she called eye movement desensitization and reliving (EMDR). Subsequently she has also published a book (Shapiro, 1995) on the subject. The therapeutic technique was described as involving eliciting from the client sequences of large-magnitude, rhythmic saccadic eye movements, while holding in the mind the most salient elements of a traumatic memory. The client is asked to come up with a prototypical image which symbolizes the area of trauma. After being subjected to a set number of eye movements they are encouraged to talk about what remains of their concerns, and what has come up for them during this brief period of time. When they come to the end of discussing this a fresh image is evoked, symbolizing the imaginal or verbal material which has emerged. The process is then repeated until the client reports a significant reduction in the subjective units of distress (SUDS). This appears to result in rapid reduction in anxiety, changes in cognitive assessment of the memory, and cessation of flashbacks, intrusive thoughts, and sleep disturbance. In her book Shapiro writes about what she calls accelerated emotional processing, and there is some resonance with the work of Foa's group, described in the previous section. It is also interesting to recall that in Wolpe's work (described in the section on desensitization) merely bringing upsetting images to mind, and holding them in awareness, tended to alter both their content and their meaning, with a subsequent drop in affect.

However, the literature suggests that EMDR is a far from uncontroversial area. There are a number of review articles pointing out that many of the studies reported are characterized by serious methodological flaws, including failure to use repeated objective measures, and the use of other interventions in combination with EMDR (Acierno et al., 1994; Lohr, Kleinkrecht, Tolin, & Barrett, 1995). Nevertheless, there are many reports of rapid improvement with this technique, particularly where there are disturbing memories, and a recent meta-analysis found as much evidence to support this technique as there is for other efficacious approaches to PTSD (Van Etten & Taylor, 1997). Research questions which remain to be answered decisively include whether or not the rapid eye movements are a necessary component, whether or not relaxation facilitates the process, and whether any additional benefit is gained above merely repeating the presentation of the image.

6.14.4.6 Thought Stopping

It might appear that therapeutic strategies in which the patients are directed to immerse themselves in fearful imaginings, or relive distressing memories, would be in direct contradiction of an approach like thought stopping, which aims to suppress thoughts or images. However, this approach was used for a number of years, and was sometimes considered useful in the treatment of obsessions and other unwanted thoughts and impulses.

Thought stopping has been another controversial technique, with some review articles sounding a cautionary note. Where there have been positive results the emphasis has not been on blocking the obsessional cognitions as such, but on stopping before attempts to covertly neutralize the upsetting thoughts or images can occur. Thus, as a behavioral strategy the best use of thought stopping would be in the area of response prevention, that is, the prevention of covert rituals (Salkovskis & Westbrook, 1989). This would mean that in order to decide whether an imaginal exposure approach or a thought stopping approach was relevant one would need a functional analysis of the cognitions concerned to decide which strategies were appropriate for which parts of the problem.

6.14.5 WORKING WITH IMAGES IN COGNITIVE THERAPY

6.14.5.1 Images and Memories in Cognitive Therapy

Internal reality is said by Beck (1976) to comprise meanings, significances, and imagery, and we are advised to work both with images and thoughts. Sometimes in therapy an image seems to resonate more fully with an expressed emotion than the thought expressed in words. For example, the anxiety of an agoraphobic who thinks that they might fall down makes more sense to us when they describe an image of this fall, in which they see a crowd gather, summon an ambulance and take the patient to hospital, where they are kept against their will. This type of difference between the first negative automatic thoughts reported in a situation, and the spontaneous images which are described, has been exemplified in a paper by Wells and Hackmann (1993). In this paper the negative automatic thoughts and images about illness and death were studied in a group of hypochondriacs, and material presented highlights the extra, idiosyncratic layers of meaning depicted in the images. It is clear that for many hypochondriacs the feared catastrophe is not just illness or death, but the imagined interpersonal cost to them of these events (such as being neglected in hospital by relatives, or dying and ending up in Hell, or alone or trapped in a coffin with full awareness, or being able to witness one's family, carrying on quite happily without one).

Thus, attending to the content of images can help people get a "handle" on why they are getting upset (see Gendlin, 1988) and can also provide a quicker route in to what Barnard and Teasdale (1991) would call the implicational level of meaning which tends to be more poetic and more idiosyncratic than the less colorful, shared level of propositional meaning. It is also true that, as Lang (1977) points out, images contain both stimulus and response elements, and thus give access to more of any particular fear structure. Of course, when working with verbal material in cognitive therapy we can access more meaning of a more idiosyncratic nature with judicious use of questions such as "What did that mean to you?," "What was the worst thing about that?," and "Can you tell me a bit more about that?" These are the type of questions used in the "downward arrow" technique (e.g., Greenberger & Padesky, 1995), which is a standard technique in cognitive therapy to elicit the full meaning of the appraisal leading to the strong emotions reported in therapy. What is being suggested here is that spontaneous images accompanied by high affect can be a rapid way into the system.

In cognitive therapy there are a number of aspects of imagery one might choose to work on. These include unpacking the meaning encapsulated in the image, attempting to transform it, and examining and working on beliefs about the meaning of actually having the image. It is also possible to work on memories, which are imaged by the patient when asked to relive the remembered experience. Once again the meaning given to the memory can be explored, and sometimes transformed using imagery techniques.

6.14.5.2 Eliciting Images and their Meanings

Greenberger and Padesky (1995) advocate staying with questioning and careful reflection until cognitions arise which seem to be an adequate match for the level of emotion experienced. They pose a series of useful questions such as "What does this mean about me, my life, other people, the future?," "What am I afraid of?," "What might happen?," "What images and memories do I have in this situation?" Whilst doing this visual images or sensory impressions can occur in any modality, reflecting the present, the past, or the future, and these can be literal or metaphorical images. Any of these images can be used in cognitive therapy, in the sorts of ways described in subsequent sections.

It is also possible to enquire directly about the presence of an image. For example, in agoraphobia clients are often rather vague about the feared catastrophic consequences of their bodily symptoms of anxiety, whilst their avoidant behavior suggests that they are quite frightened. Asking them whether they had a picture of what might happen in a given situation often provides graphic information about the exact nature of the feared catastrophes. For example, one person might picture themselves as having collapsed in a crowded place, and being totally ignored, whilst another might have an image of a large crowd gathering and an ambulance arriving with a wailing siren.

Sometimes it is possible to spot when a client has a spontaneous image whilst describing something from the way they point, gesture, or direct their gaze. One woman with hypochondriasis was describing what she thought would happen when she was dead, and indicated with her hands how her Elvis flag would be draped across the coffin, whilst her family were grouped around it. This was a cue for her therapist to enquire whether she was picturing this at the time, which she was. This then led her say that she was, but that she habitually tried to suppress this image, as she feared that if she pictured it this would make it more likely to happen. This type of information is also useful for the therapist, as it is possible that her voluntary efforts to suppress the image are likely to make it recur more frequently, thus maintaining her distress, as in thought suppression experiments (Trinder & Salkovskis, 1993).

It is also important in some disorders, such as obsessions, to enquire about the existence of neutralising images. Sometimes these have the function of compulsions, in that they are evoked voluntarily in order to neutralize unwanted obsessional intrusive thoughts. For example, someone who had a spontaneous image of her husband being ill might deliberately try to form a positive image of him looking healthy and well. Such different functions and origins of the images have to be taken into account when planning a strategy, whether the treatment is a cognitive or a behavioral one.

Images are common in PTSD. In this case they are frequently fragments of disturbing memories, which press into conscious awareness at frequent intervals, to the distress of the individual. Whilst they are usually closely related to the trauma they are not always identical to it. For example, one man was traumatized by having to witness the body of a woman who had had her head chopped off. He had recurrent images of her husband swinging the chopper towards her, which he had not actually seen. However, the image seemed to have input from an earlier, linked memory of seeing his father attack his mother with chopping movements when he was a boy. The image of the murder was accompanied by the sense that he should have been able to prevent it, an inappropriate response since he was not there, nor did he know the people. However, the response was identical to the way he had felt as a boy. Images which appear to be fragments of memory, or which appear to have much input from memory in sensory modalities are often triggered by sensory cues, which incidentally can also sometimes trigger the distress without the patient consciously remembering the original event. This brings us back to the starting point of allowing enough time for the patient to stay with the strong emotion evoked, for any associated thoughts, images, and memories to come into awareness. Needless to say this can temporarily increase affect as meaning is accessed, and may be resisted at times by patients.

It is also important to note that images which seem in fact fragments of upsetting memories, or amalgamations of several of them, are also present in other Axis I disorders (Hackmann, 1995; Hackmann & Clark, in press; Hackmann & Surawy, in press; Wells & Hackmann, 1993). Other authors have also noted the intrusion of traumatic memories during depressive episodes (Brewin, Hunter, Carroll, & Tata, 1996; Kuyken & Brewin, 1994).

Once images have been elicited the therapist needs to help the patient understand the meaning attached to them. Images can be considered at the level of automatic thoughts, in which case the therapist can ask what the image means to the person, what has led up to the events in the image, and what is the worst thing about it. Typically this sort of question will give rise to a set of negative automatic thoughts, which can be worked on using verbal techniques, or imagery techniques as described below. It is also important to find out what sort of beliefs the patient has about actually having the image. For example, do they see it as a prediction of what will happen in the future, or do they think that such images can affect reality in some way? If so, such beliefs may also need to be worked on in therapy.

Further questions about what the image means about the individual, other people, and the world in a more general way can lead on to the elicitation of conditional and unconditional core beliefs, which can also be worked upon at a later stage.

Once all the meaning and sensory data in the image has been unpacked a useful bridge can be made back to early experience by asking when in life the client can first remember having the types of thoughts and feelings and sensory experiences reflected in the image under consideration. Often this takes the patient right back to traumatic memories from childhood which appear to have set the scene for later maladaptive schemas (e.g., Wells & Hackmann, 1993). For example, a patient with an obsessional fear of getting AIDS repeatedly visualized himself in hospital, in a white, cast-iron bed, all alone because he is blamed by others for contracting the disease. In the patient's mind there was a direct link between this recurrent image and a memory of lying in hospital with a broken arm, alone and not aware of the pain so much as the fear of his father blaming and rejecting him for having had an accident. To his amazement he realized that the bed in the hospital in the image and in the memory was in fact the identical white, cast-iron bed with the same white sheets and blankets. Having located significant memories in this way (or if they come up spontaneously in therapy) it is then possible to work on early memories using imagery techniques such as those described below, often with profound results.

As mentioned above, some of the images clients bring are symbolic rather than literal images. For example, someone feeling exhausted and resentful about the way in which their family depends on them may picture themself with their family in a canoe, having to row them all upstream in the Amazon. Similar questions can be used to explore the meaning of this type of image, and its possible history in the life of the individual, before proceeding to consider ways of transforming its meaning (Edwards, 1989). This work considers thematic rather than symbolic content of the images or dreams being presented, in the sense that the client provides their own hunches about the history and meanings of the images, rather than the therapist trying to interpret them in the light of what the therapist might consider to be the usual symbolic meanings (Freeman, 1981).

6.14.5.3 Transforming Images and their Meanings

The meanings elicited from consideration of the image can be worked on using the full range of verbal techniques and behavioral experiments familiar to the cognitive therapist. The encapsulated meanings can also be changed by altering the image in the modality or modalities in which it was experienced. A short summary of possible interventions to transform images and their meanings at the level of negative automatic thoughts will now be given.

In many anxious images a scenario is pictured, in which the worst possible outcome has been visualized, and the image is effectively frozen in time at this worst point. In such a case it may be sufficient to simply let the image run on in time. For example, a client who was afraid of being sick on arrival at a party, and thus totally ruining the evening for everyone, was helped by running his recurrent image on in time past the point where it usually stopped (i.e., when he had just vomited) to discover that as it unfolded people appeared in the image to help him clear up, were sympathetic, and encouraged him to stay on until he felt better. Thus, he could appreciate the fact that the evening might not in fact be ruined. This was easier to believe once he had also tried picturing what might happen if his girlfriend vomited, rather than him (a decentring technique which is often useful in social anxiety).

Another client was terribly distressed by recurrent images of her own gravestone, and the happy faces of her husband and child when they visited it. Verbal discussion had helped her to see that this image was only an image, and did not necessarily depict what would happen in the future, but without lessening her distress. What did help was to imagine herself alive and well, and looking at this image on a television. She was then able to picture herself switching off the television, and driving away from the house. This changed her beliefs about the meaning of having the image, in the sense that she no longer felt that it reflected her future, but was only a product of her fearful mind. This simple intervention got rid of both images and nightmares on this theme, which had been tormenting her. Putting the image on the screen gave her the message that after all it was only an image, and one which she could control. This maneuver is also useful in dealing with any very frightening imaginal material, since the image can then be switched on or off, or made smaller or dimmer, as a prelude to dealing with it further. In these cases the meaning that is changed is at a meta-level: what is changed is the meaning of having the image, rather than the meaning of the image. Similar techniques can be used in the treatment of distressing images following trauma. Putting an image or vivid memory of a screen and altering it can help keep affect at a managable level, and reinforce the idea that what happens in that working space is not what is happening in the present: it is only an image or memory, and belongs in the past. Further work can then also be done to change the content if appropriate.

In some cases when one enquires about images those that are reported are not accompanied by much affect, and are rather small, or distant, blurred, or foggy. In such a situation the patient can be asked to zoom in on the image, and make it bigger or clearer, in order to examine and work on the content.

Where there is an absence of positive images, for example in the hopeless depressive attempting to picture the future, it may be helpful to prompt the patient to generate detailed, positive images. For example, they can be asked to picture themselves in the future when the depression is over, and they can be asked to picture where they are living, with whom, and what work they are doing, and what their hobbies are. They are to imagine who is there and what is actually happening at given points in time. This type of work can subsequently have a motivating effect on the patient (Layden, personal communication).

In a similar way where the patient is about to try some new behavior in real life it can be very helpful to imagine carrying out the desired coping behavior. This gives the opportunity for a useful rehearsal of the skill, and can then either go into memory as a success experience, or if snags arise in the imaginary scenario more verbal discussion and imagery work can be done to deal with these.

Another useful technique is to abandon the spectator position. In social phobia it has already been mentioned that individuals are likely to have very distorted images of themselves, as seen from an external point of view (i.e., as an observer might see them). Since these images can be shown to be inaccurate, using feedback from others, or video feedback, patients can be advised to ignore them, and focus instead on the external environment, and the true reactions of others. In a similar way people with health anxiety can have images of what they imagine is happening inside their bodies, and can learn to ignore these or replace them with more realistic mental pictures.

6.14.5.4 Working with Beliefs about Having Images, Intrusive Memories, and Nightmares

Often patients who experience affectively laden intrusions are further distressed about the meaning of actually having the intrusions. They may believe that these intrusions reflect reality, for example, that they foretell the future. Or they may believe that they are a sign that they are losing control or going mad, particularly if attempts to banish them lead to increased occurrence of the intrusions. Sometimes they believe that having particular thoughts or images may mean something bad about them as a person, or may directly affect what will happen (e.g., thinking about illness can make you become ill, or thinking about being well or happy could tempt providence). Such beliefs can be tackled in therapy using verbal techniques and behavioral experiments.

6.14.5.5 Working with Core Beliefs Using Imagery Techniques

A variety of verbal and behavioral techniques are also available for use in changing core beliefs (Beck, Emery, & Greenberg, 1985; Beck, Rush, Shaw, & Emery, 1979). These can be used to examine both conditional and unconditional beliefs about the self, the world, and other people. However, there may be ways of supporting this verbal work with imaginal material in ways which enhance the emotional shift, and help to affirm and strengthen more adaptive ways of viewing life.

The cognitive model of emotional disorder suggests that our negative automatic contents of consciousness reflect our core beliefs, as activated by present events. These beliefs were formed as a result of early experience. Very often there are particular early memories which seem to reflect core beliefs as they emerged in a person's life. These memories can be accessed and transformed using imagery techniques, as described by Edwards (1990), Layden, Newman, Freeman, and Byers Morse (1993), and Smucker, Dancu, Foa, and Niederee (1995).

Layden et al. (1993) describe the sequence in which one can work when attempting to "repair" traumatic early memories. The first step is to notice when a negative core belief is activated, and instruct the client to dwell on how they feel emotionally, in terms of bodily sensations, and what sorts of thoughts and images they are having. Once they have dwelled on these contents of consciousness they are asked whether there is an early memory which is linked to such emotions, sensations, and thoughts. Very often one or more traumatic memories come to mind. Once a memory has been selected as seemingly important in the formation of the negative core belief the patient is instructed to close their eyes, and relive the memory, frame by frame, reporting their experience aloud, and the meanings they are giving to events. Once all the painful meanings have been discussed and challenged where appropriate using verbal techniques it is often extremely helpful for the patient to mentally replay the memory, bringing in any corrective information which has been pinpointed during discussion. This can be done in many ways. For example, the adult self can visit the unhappy child, and present an adult perspective on their predicament, and the conclusions they have drawn from it. Also, other coping and rescue factors can be highlighted.

To give an example, a man suffering from agoraphobia had great anxiety on going far from home, accompanied by fears of becoming ill in some way and images of being taken to hospital, kept there indefinitely against his will, and never being visited. Whilst attempting to transform one such image of being trapped in hospital he retrieved a traumatic memory of being taken to hospital when he was three, left there by his parents for three days without explanation of where they had gone. At the time he had become extremely afraid that, as the unwanted fourth son of a poor family with a sick mother, he had been gladly abandoned by his parents. The transformation of the meaning of this memory image was effected by having the adult self visit his parents in the hospital, and warn them not to leave the child there without explaining why they were doing it, and reassuring him that they loved him. This was accomplished after reviewing through discussion in therapy the evidence he had that in fact his parents did love him, and also that back in the 1950s people did not realize how traumatic a lonely hospital stay could be for a small child. This intervention had the effect of abolishing his panic attacks for several months, during which additional work was done on his core beliefs.

Quite fanciful scenarios can be utilized to good effect. One patient who had concluded at an early age that she was unlovable after certain messages were given to her by her mother repeatedly saw her child self as unattractive, with the word "precocious" over her head. In imagination she visited an "inner guide," whom she visualized as a wizard, and asked him to show her in a crystal ball what sort of a child she actually was. In the crystal ball many pleasant images of herself appeared, including one of herself aged six putting a hot water bottle in her parents' bed. This image had the word "kind" over her head, and was accompanied by a deep and lasting shifting of the affect associated with memories of her childhood, and her feelings about herself.

More orthodox schema work can also be reinforced by the use of symbolic material. For example, one patient had many unconditional negative core beliefs about herself and others, to the effect that she was an emotionally deprived person, whom others should look after unconditionally, and never leave her to fend for herself. If they did it meant that she had been rejected and abandoned in a harsh world, and could trust no-one. In therapy she was working towards being able to stand criticism, and take care of herself without a catastrophic emotional response. She was greatly supported in this by reading the story of Vasalisa, whose mother died when she was small, but left her a doll who lived in her pocket, and helped her decide what to do when the going got tough. The patient found this a most useful metaphor for her new sense of herself as supported, but able to be independent, with growing intuition and skills of her own.

Finally, it may be worth noting that some of the techniques described above which can be used to transform the meaning of early memories can also be used when working with intrusive traumatic fragments of memory. The client can be asked to bring the traumatic memory vividly to mind, and then unpack its meaning, as described above. Once the meaning has been discussed and verbally challenged the memory can be replayed in imagery, incorporating material depicting the new perspective. For example, a man whose father had died in an explosion discovered that the meaning behind his intrusive image of his father's body was the idea that his father's spirit had not been able to leave the scene of the accident. Imagining his father's spirit as now being free, and able to travel to his favorite place and then be released provided relief, and the images of the body disappeared.

6.14.6 CONCLUSION

Clinical psychologists who work within the scientist–practitioner tradition would probably agree on a model of human functioning which proposes that in a given situation conscious and unconscious appraisals will be made, leading to a set of automatic reactions (such as autonomic changes and probably some automatic adjustments in information processing, together with behavioral reactions (such as escape, avoidance, etc). Both automatic and behavioral reactions may change the perceived stimulus situation to some extent, so fresh appraiasals may be made. For example, in a panic attack bodily changes may be perceived, and catastrophically misinterpreted (perhaps in an image of an imagined heart attack) resulting in an escalation of anxiety. Also, in social anxiety a person might talk quickly, and attempt to fill silences for fear of being thought boring, but might then get a distorted image of themselves as babbling or talking terribly quickly, from which they might conclude that that is how they are being seen by others at that moment.

The therapist can attempt to break in to apparently closed systems of situations, appraisals, and automatic and behavioral reactions in a number of ways. In life people are continually appraising stimuli for their meanings, and then reacting accordingly. If we agree that this takes place partly consciously and partly unconsciously then there need be no disagreement between various schools of thought, but instead they can be seen to be focusing on different aspects of functioning.

Images and memories with sensory components form a sizable proportion of the conscious appraisals of many people, and it is also possible to bring them under voluntary control, at least to some extent. Since they can contain both stimulus and response elements (Lang, 1977, 1979) they can provide a useful working space in therapy in which to attempt to change appraisals of stimuli, or of automatic or behavioral reactions to them.

There is a certain amount of literature to support the view that emotion is more closely linked to mental contents with sensory components than those in the verbal modality. In most individuals conscious experience is a rapidly changing mix of these two ingredients. It has been hypothesized by Borkovec and Inz (1990) that one of the possible functions of verbal worrying is to keep more frightening or upsetting images or memories at bay, or in the unconscious, to use the terminology of the analysts.

It is certainly true that after a traumatic experience people often try to keep memories at bay, and the fragmented memories appear to be stored in sensory modalities, and can be readily accessed by situational cues, to the extent that in PTSD people can find themselves involuntarily reliving various aspects of the trauma. As time goes by (in cases where the problem is successfully resolved) a narrative version emerges, which incorporates details previously forgotten, and which is no longer fragmented or disjointed. This narrative can be run through in imagination or conversation without enormous distress, and the more sensory type of memory is less likely to be triggered by sensory cues. This interesting process has been described by Jaycox and Foa (1996), and is also consistent with theoretical models such as those of Brewin, Dalgleish, and Joseph (1996), Dalgleish (1997), Ehlers (1997), Ehlers and Clark (in press), and others discussed by Power (1997).

It may be that such theoretical accounts of PTSD have something to tell us about other emotional problems. It has been noted above that in various anxiety disorders there are spontaneous images in anxious situations, which not only depict possible catastrophes which might occur now or in the future, but also are often rich with sensory and interpersonal material which appears to be linked to past experiences in which there were similar themes and stimuli. There is evidence that bringing recurrent upsetting images into full awareness can often spontaneously evoke such traumatic early memories. Both images and memories echo current concerns and important themes for the person, encapsulating idiosyncratic meanings, linked to core beliefs.

A wide range of techniques are available for use in this "working space," and they seem to share many characteristics. They allow rich, multifaceted material to emerge into full consciousness, and provide opportunities for the incorporation of corrective information, and the possibility of moving towards storing material in a semantic, orderly form, which does not intrude, and is not so affectively laden as when it was stored in a more sensory mode. It is interesting to note that in a number of the therapeutic approaches described merely bringing upsetting images or memories to mind repeatedly seems often to result in spontaneous changes over time, with the imagined material becoming less emotionally charged, less vivid, and less threatening in meaning. In other cases imagery techniques can be used to access meanings, which can then be challenged using verbal discussion techniques, behavioral experiments, and direct restructuring of images and memories. There also appear to be direct effects on behavior from the imaginal rehearsal of possible future scenarios. However, this whole area has not been extensively researched, and much interesting work remains to be done.

6.15.1 INTRODUCTION

Group therapy is widely used as the context of treatment for patients with a variety of problems and concerns. In a recent survey of mental health providers in a middle-sized American city, it was noted that 72% of the providers made the option of group therapy available to their patients (Rose, 1998a). There are many types of group therapy, one of which makes use primarily, though not exclusively, of cognitive and behavioral procedures. The purpose of this chapter is to describe the rationale for, review research concerning, and present one general approach and the techniques commonly applied in this form of group therapy primarily for adults. Unfortunately, in the existing literature, the role of the group is rarely explicated (see Rose, Tolman, & Tallant, 1985, for a review of the cognitive-behavioral group therapy literature until 1984).

Because of this neglect the potential use of the group as a set of interventions in itself in administrating cognitive and behavioral procedures is described in this chapter. Because the approach lends itself to evaluation and specific description of its primary intervention, assessment, and generalization strategies, cognitive-behavioral group therapy appears to be growing in popularity among practitioners and patients. Its relevance in particular for women has been described by Wolfe (1987) and for minorities in studies by La Framboise and Rowe (1983) and Comas-Diaz and Duncan (1985).

Cognitive-behavioral group therapy (CBGT) refers to an approach that occurs in groups and makes use of behavioral (e.g., modeling and reinforcement), cognitive (e.g., cognitive restructuring, self-instructional training, problem-solving), relational change methods, and group procedures to enhance the coping skills of the participants and to resolve or ameliorate relational problems they may be experiencing. Coping skills refer to that set of behaviors and cognitions which facilitate adaptation to stressful or problematic day-to-day situations. Some coping skills which participants learn in CBGT are systematic problem-solving, relaxation, meditation, imagery, techniques for "decatastrophizing events," correcting other cognitive distortions, being appropriately assertive, distancing or objectifying one's pain or strong emotions, communication skills in dealing with others, negotiation, and making more effective use of social networks and increasing social-recreational skills. Many of these skills are both target behaviors and a means of intervention for learning more specific target behaviors.

Group treatment approaches in general when compared with individual approaches seem to fare favorably. A meta-analysis (Toseland & Siporin, 1986) reviewing all group vs. individual therapy comparisons (many of which were cognitive and behavioral) showed evidence that groups are at least as effective and sometimes more effective than individual treatment and more efficient in that more patients can be dealt with effectively for the same cost. This finding was confirmed by Tilliski (1990) who used only those studies from the Toseland and Siporin review that contrasted group, individual, and a control group. In all cases, regardless of theory or problem focus, there was no difference between treatments and significant differences between treatment and the control group. Since that time several studies involving CBGT have appeared which also support the equivalency of individual and group therapy and their greater effectiveness than control groups in the treatment of a variety of presenting problems. For example, Spence (1991) demonstrated that CBGT was equivalent to individual cognitive-behavioral therapy and both were more effective than a wait-list control in the treatment of chronic occupational pain. Oneytt and Turpin (1988) found that a six-week cognitive-behavioral group treatment was more effective than a control group but equivalent to individual general practitioner appointments in the reduction of benzodiazepine use and anxiety. All changes were maintained at 15-week follow-up. The results are confounded somewhat by the fact that the general practitioner may not have used cognitive-behavioral methods. Teri and Lewinsohn (1986) also found that both individual and group behavioral treatment were equivalent and both were more effective than a wait-list control in the treatment of patients with moderate depression.

Support for the effectiveness of CBGT has also been demonstrated in studies in which CBGT was compared to wait-listed and other approaches. When Wolf and Cowther (1992) compared CBGT with behavioral treatment for 41 bulimic women, both were more effective than an extreme weight control method in terms of reduced bulimic tendencies. CBGT was also more effective than the behavioral treatment measures in the treatment reduction of severity of psychopathological symptoms and preoccupation with dieting. Lee and Rush (1986) had similar results with 30 bulimic patients. Those receiving five weeks of CBGT reduced their binging and purging behavior significantly more than those in a wait-list control group. However, only four of the CBGT patients showed a full remission of the binging and purging behavior.

When Bottomley, Hunton, Roberts, and Jones (1996) compared nine patients in CBGT to a eight patients in social support group and to 14 "decliners" for newly diagnosed and psychologically stressed cancer patients, they found that the CBGT patients significantly improved their coping styles in comparison with the other two conditions. At three-months follow-up, the differences washed out possibly because two CBGT patients had died.

Ehlers, Stangier, and Gieler (1995) compared cognitive and behavioral methods carried out in groups with intensive or standard dermatological treatment. They found that the behavioral treatments for atopical dermatitis resulted in significant improvement in skin condition and in topical steroids used when compared to dermatological condition alone, at one-year follow-up. Once again, the group factor and the behavioral methods were confounded in the experimental condition.

Fals-Stewart, Marks, and Schafer (1993) compared a behavioral group therapy condition ($n=30$) consisting of group exposure and response prevention with an individual therapy condition ($n=31$) using the same methods and a relaxation control condition ($n=32$). The subjects were randomly assigned to the conditions. Patients in all three conditions showed stress reduction at the end of treatment, but only in the behavioral conditions were the gains significantly maintained at the six-month follow-up.

Lutgendorf, Antoni, Ironson, and Klimas (1997) tested the effects of a 10-week cognitive-behavioral group stress management program on mood and immunologic parameters in HIV-seropositive gay men whose disease had progressed to a symptomatic stage. The patients were randomly assigned to the CBGT ($n=14$) or a wait-list control group ($n=12$). At the end of the 10 weeks patients in the CBGT condition significantly decreased self-rated dysphoria, anxiety, and total distress. The intervention also decreased Herpes simplex virus-type 2 (Hsv-2) immunoglobulin G antibody titers. No such changes were found in the control group. There was no follow-up measurement.

Subramanian (1991) found that 39 chronic pain patients in eight weekly sessions of CBGT improved significantly more than a wait-list control ($n = 20$) in the areas of physical and psychosocial dysfunction, but showed no difference in the experiencing of pain. Group strategies as well as cognitive-behavioral strategies were described in this study. However, in a follow-up study, Subramanian (1994) found that the gains of a subsample that could be located were not maintained. However, no specific steps in and after the therapy program had been taken to achieve maintenance.

Patients in CBGT in a number of before and after multiple cases without control groups have consistently shown significant change over time and for the most part these changes were maintained 2–3 months following treatment. These studies include coping with generalized anxiety (Lindsay, Gamsu, McLaughlin, Hood, & Espie, 1987; Power, Simpson, Swanson, & Wallace, 1990), adaptation problems of recently divorced women (Graff, Whitehead, & LeCompte, 1986), managing one's depression (Abraham, Neundorfer, & Currie, 1992), social phobia (Enright, 1991), obsessive-compulsive disorders (Krone, Himle, & Nesse, 1991; Van Hoppen, Rassmussen, & Eisen, 1991), insomnia (Kupych-Woloshyn, MacFarlane, & Shapiro, 1993), and a heterogeneous population of 531 patients suffering from various psychiatric problems in intensive CBGT at a private psychiatric clinic (Manning, Hooke, Tannenbaum, & Blythe,1994).

Although each of the above researchers treat the given problem area in groups using cognitive-behavioral and/or behavioral intervention strategies, most use different combinations of these techniques and, as already mentioned, a few describe specific uses of groups in the treatment process such as member modeling and building cohesion of the group. In summary, modest support for CBGT can be identified. Usually in the control group and databased case studies, the group factor and the cognitive-behavioral techniques are confounded, thus making interpretation of the findings unclear as to whether group or the cognitive-behavioral strategies are the major causes of change.

Because of the variations mentioned above, different kinds of cognitive-behavioral approaches to CBGT exist. Some primarily rely on cognitive, relaxation, relational, and didactic procedures, while others integrate with the cognitive procedures extensive behavioral methods such as modeling and reinforcement into the treatment program. Only a few make specific uses of the group. Because of our clinical and research experience with a model of CBGT that incorporates group techniques into treatment, the purpose of this chapter is to present a cognitive-behavioral model that indeed makes use of the group. In this chapter the specific model that includes the extensive use of group methods and a focus on group variables that impinge on outcome along with the use of cognitive-behavioral procedures is referred to as cognitive-behavioral interactive group therapy (CBIGT), while CBGT refers to all group models using cognitive-behavioral methods, whether explicit use of the group has been determined or not.

6.15.2 THE IMPLICATION OF THE GROUP IN CBIGT

Originally the group was used in therapy because of its convenience and efficiency in treating more than one or two people at the same time. As many scholars of group therapy have noted, it has a number of other advantages (e.g., Yalom, 1985, p. 3). Improved opportunities for assessment is a major contribution of therapy in groups. The group therapist has the opportunity to observe live interactions as opposed solely to second-hand accounts of interactions and make solid conclusions as to social skill strengths and deficiencies. He or she can hear the cognitive distortions typical of many patients being played out in the group. This is possible only insofar as there is broad participation among the patients which is the focus of many interventions in CBIGT.

The group provides the patient with a source of feedback about those behaviors which are irritating or acceptable to others and about those cognitions which can be viewed as distorted or dysfunctional. In CBIGT, participants are trained to help each other be concrete in the formulation of problem situations and the cognitive, emotional, and behavioral responses of the patient to those situations and to identify specific goals towards which intervention is aimed.

Another advantage of using the group in CBIGT is the frequent and varied opportunity for mutual reinforcement which for patients is often far more powerful than reinforcement by the therapist only. Each patient is given the chance to learn or to improve his or her ability to mediate rewards for others in social interactive situations (with acquaintances, friends, family members, acquaintances in other groups, fellow therapists, or employer). The group therapist in CBIGT creates situations in which each patient has frequent opportunities, instructions, and rewards for reinforcing others in the group. In CBIGT, special exercises have been designed to train patients specifically in mutual reinforcement, and often extragroup tasks (homework) are used to encourage them to practice reinforcement skills in the real world.

High levels of reinforcement, among other techniques, contribute to the cohesion of the group. As Yalom (1985, p. 49) argues, group cohesion is the equivalent in groups to relationships in individual treatment. At least in the early phase of therapy, cohesion must be high if other methods are to be maximally effective.

If cohesion is high, the group creates the opportunity for the group therapist to mobilize the members to use of a wide variety of coping skill training procedures that are either unavailable or less efficient in the therapeutic dyad. For example, the most effective way of systematic problem-solving is in the group. In the "brainstorming" phase of problem-solving, the multiplicity of patients and patients' experiences results in numerous ideas and suggestions. The group also provides a large number of models, role-players for behavioral rehearsal, manpower for monitoring, and partners for use in a "buddy system."

In CBIGT, as well as most other CBGT models, members are expected to carry out homework or extragroup tasks which are cognitive, behavioral, or both, to practice what they have learned in the group. Much of the program in CBIGT is designed to prepare the members for completing those tasks. If appropriate norms are established, the group serves to enhance the design through group feedback and mutual supervision in subgroups, and to reinforce the completion of extragroup task completion if the members report publicly at the beginning of the following session what they did for their task during the week.

Negotiating rather than assigning homework tasks in CBIGT and the use of extensive feedback from members and brainstorming increases the power of the members and reduces the excessive didactic quality of many other models of CBGT. Specific questions on weekly postsession questionnaires (see Table 1) keeps the therapist in touch with the group's evaluation of their own participation and power in the group.

Finally, Yalom (1985, p. 14) points out the importance of helping others (altruism) in facilitating therapy in groups. Although he refers to insight-oriented group therapy, the same appears to be true for CBIGT provided that the therapist creates conditions which permit patients to help each other. In this way the participant is not only a patient, he or she is also a co-therapist–teacher within the given structure. This appears to increase the participant's sense of self-efficacy or the belief that he or she can perform in such a way as to achieve a desired outcome (Bandura, 1977). Yalom (1985, p. 8) also reminds the reader of the principle of universality. Patients experience that they are not the only person with the given problem, as serious as it may be.

Of course, groups are not without disadvantages. The time allotted to each individual is drastically reduced in most groups compared to individual treatment. Thus, individualization of patients may suffer. If the group process is utilized in treatment, the amount of material covered is less than when the group process is ignored. In addition, it is difficult to assure the patients of the confidentiality of their comments, even though the therapist emphatically points out its importance. For this reason, some individuals in group therapy are less likely to self-disclose relevant material than they would in individual therapy. However, many others are encouraged by the modeling of other members to self-disclose more readily. Usually as the group progresses, interpersonal trust increases, and the patients become more comfortable with self-disclosing significant concerns. Another danger of CBGT is its tendency to become excessively didactic because of the amount of material to be disseminated. This didactic quality may reduce the cohesion of the group and reduce the benefits which might otherwise ensue. Also, the opportunity for altruistic activities is diminished. For this reason, in CBIGT group therapists are encouraged as early as possible to create conditions that maximize patient participation and self-determination. The use of small group

Table 1 Example of a postsession questionnaire.

15. What specifically did you find useful in todays session?
16. What specifically did you find unhelpful in todays session?

exercises especially in subgroups (see Rose, 1997, for a description of most of these) also enhances broad participation.

6.15.3 THERAPIST ACTIVITIES IN CBIGT

One cannot merely assume that if a problem and the appropriate coping skills are identified, one can then intervene at any time in the therapeutic process with the best techniques available and help the patient to solve it. In CBIGT just as in other group therapies, one can identify a number of sets of activities each of which is linked to unique and overlapping therapist functions. They are somewhat overlapping in time and in content. Differentiating these sets is useful insofaras each set of activities provides a guide for the group therapist as to when emphasis should be shifted. These include a pregroup planning, an orientation, an assessment, an intervention, a generalization and termination, and a postgroup set of activities.

6.15.3.1 Pregroup Planning

In planning for therapy, the CBIGT therapist must establish the group's purposes, assess potential membership, recruit members, decide on the group social environment or structure, and create the group's physical environment. In determining the group's purposes, the group therapist can draw on several sources. Based on experience with patients in the agency or community, the agency may have identified a need for a certain type of program. Patients may have been requesting help for certain types of problems for which help is not generally or readily available. To the degree that these needs can be translated into behavioral or cognitive responses to identifiable problematic situations, the CBIGT approach can be considered. Decisions must be made as to the theme of the group, group size, number of therapists, frequency and length of sessions, a sufficient number of candidates for the group, and group composition.

In citing the literature above, it appears that most cognitive-behavioral groups have a theme, that is, all patients in the group have similar problems. A few practitioner–researchers (e.g., Flowers & Schwartz, 1985; Manning et al., 1994) also use CBIGT to deal with more heterogeneous groups (i.e., groups consisting of persons with diverse presenting problems) with positive results. Many of the homogeneous groups, although comprising members who have similar presenting problems, are diverse in terms of race, gender, and ethnic background, although in most of the reports from the literature the groups are predominantly White middle class. Some groups are homogeneous in terms of gender and race. Some single case research and descriptions of clinical experience point to the efficacy of CBGT (although not necessarily CBIGT) approach with Hispanics (see Comas-Diaz & Duncan, 1985), Native Americans (La Framboise & Rowe, 1983; Schinke & Singer, 1994), and economically disadvantaged depressed women (Azocar, Miranda, & Dwyer, 1991). Wolfe (1987) makes use of all-women groups because consciousness raising is a component of the CBGT model she employs. Wolfe (1987) asserts that CBGT and in particular, rational emotive therapy in groups, seem to come the closest to meeting the criteria for feminist therapy. Sometimes all-women groups exist by default rather than by plan as in the case of many parents groups or groups of depressed persons where only women sign up. All-men groups in CBGT can be found for male abusers, anger management groups in prisons, and men who are HIV positive.

At least two kinds of basic organization for therapy groups can be identified. The first is open-ended groups in which new group participants come at any time in the history of the group and leave at any time. These are usually found in institutions although some community groups are organized in this way as well. It is a more common model with support groups than CBGT groups. The model duration of most open-ended groups is approximately a year, although some groups may go on for much longer. However, participants may stay for any length of time, and they often come and go sporadically. The session length varies from one to two hours.

The second type of organization is closed groups which have a fixed beginning and fixed end-date for all participants. Most of the available research is on this type of group and most cognitive-behavioral community groups are closed. Although there are many exceptions, most closed groups last from 6–16 sessions once a week for one and a half to two hours. The modal number is eight. Experience indicates that 12–16 sessions are required to achieve complex or multiple goals. There is usually only one group therapist except in training situations. The size of the groups varies from as few as four to as many as 20 participants. However, with adults the modal number is eight, which permits participation by everyone at any given session and provides a wide variety of ideas and experiences. Most CBGT groups are sponsored by social agencies, clinics providing mental health services, schools and colleges, social welfare agencies, and private practitioners.

6.15.3.2 Orientation to Group Therapy

As part of recruitment and later during the first group sessions, members are oriented to the purposes of the group, the methods to be used, the potential goals that can be achieved, and the importance of keeping what goes on in the group confidential. An overview of the group activities and expectations are presented and discussed. As part of orientation, group contracts are often developed; these contracts establish what the patients can expect from the group therapist and the agency and what the members can be expected to do. These contracts are often in writing. Patients are also oriented to the basic assumptions underlying each of the treatment techniques used. In this way not only do patients know what is happening to them, expectations of positive outcomes can be stimulated.

In orientation, the therapist in CBIGT also introduces the patients to the use of the group as a vehicle of treatment. The use of subgroup exercises (Rose, 1997) are also initiated. The therapist draws on patient experience to orient members to the assumptions of the approach. Broad group discussion is encouraged by means of assigned tasks in subgroups and/or in exercises, which is the first step taken to enhance group cohesion.

Other means of building group cohesion are by using introductory exercises in which members interview each other, keeping the tone and interaction of the group positive, encouraging others to provide frequent mutual reinforcement, noting similarities as well as differences among members in terms of background and presenting concerns, keeping the group small, providing occasions for the patients to help each other, permitting and encouraging physical movement during the session, using humor, using role-playing, providing variation in program and program media, and providing or having the members provide refreshments (see Rose, 1989, pp. 250–251, for additional detail.).

One can also develop cohesion by enhancing the motivation of the members. Groups can serve to develop motivation primarily if the group therapist takes specific actions (see Miller & Rollnick, 1991, for a discussion of these principles in more detail as they apply to the individual therapy of people who abuse drugs and alcohol). In the first place the therapist should accept and encourage the patients to treat ambivalence or reluctance to participate as normal phenomena. No pressure is placed on the participants initially to change or to get out of "denial" either by the therapist or the other group members. The members are encouraged to review the advantages of the problem state as well as the disadvantages and to weigh the relative merits of changing or not changing. The patients are taught to identify motivational statements made by one another and to reinforce each other as they occur. Throughout the process the therapist makes ample use of empathic statements which are often emulated by the members with each other. The level of motivation is an ever changing process and requires constant attention by both therapist and group members.

6.15.3.3 Assessment

Assessment is a concept central to all empirical approaches. The purpose of assessment is to determine the specific targets of interventions and the specific coping skills to be learned, in such a way as to make them amenable to intervention, the situations in which these coping skills and other target behaviors should be applied, the social and material resources of each patient that might impinge on treatment, and the potential barriers to effective treatment. It has the additional purpose of determining whether the given group or another type of therapy might be the most appropriate setting for each potential patient. Finally, it forms the basis for establishing treatment goals.

The goals of CBIGT may be changes in the level of intensity of specific behaviors or an increase of more general adaptive coping behaviors. Among those specific target behaviors that patients have worked on in CBIGT and on which research exists have been mentioned earlier. These include reducing the extent or intensity of agoraphobia, social phobia, mood swings, obsessive-compulsive behaviors, smoking, alcohol and drug abuse, binging and purging, stress reduction, anger responses, and pain responses. Positive targets involve sleeping regularly, specific ways of making and keeping friends, increasing social activities, making more effective use of the patient's social network, improving relationships and communication skills. Another set of target phenomena are the development of coping skills which mediate resolution of the target behavior. Two kinds of coping skills can be identified, cognitive and behavioral.

Cognitions refer to thoughts, images, thinking patterns, self-statements, expectations, or other private or covert events which may be inferred from verbal or other overt behavior. Cognitive coping skills are those cognitions which facilitate coping with internal and social phenomena. Examples are skill in analyzing one's own cognitions, in labeling appropriately one's self-defeating self-statements, in observing and rehearsing new, more appropriate self-statements, and in reinforcing oneself covertly. Though important skills in their own right, some cognitive coping skills also mediate the attainment of the more observable social skills and other behaviors mentioned above or other coping behaviors. Thus, the goal of increasing cognitive coping skills is important as a means of reducing the frequency of anxiety-inducing and behavior-inhibiting cognitions, in diminishing the intensity of anxiety, and in improving social behavior (Beck & Emery, 1985; Meichenbaum, 1977). Self-statements, such as "everyone thinks I'm strange," not only may produce anxiety, but promote inaction or self-defeating action. Changing such self-statements to something like "Sure, I'm different than others in many ways, some things I like and some I'll change" may reflect a more accurate appraisal, may suggest avenues of change, is more self-respecting, may reduce anxiety, and ultimately should improve social behavior. In order to teach these coping skills, assessment involves having the patients examine each others cognitions in the situational analysis of stressful or anger-inducing situations. Checklists (e.g., see Piacentini, 1993, for a description of most of these) are also used: keeping track of one's cognitions with such procedures as Beck's (1976) three-column technique in which the patient records in the first column an anxiety- or anger-producing situation; in the second, his or her automatic thoughts or thinking errors; and in the third, types of errors found in these thoughts. These are then shared with other members of the group.

Another set of cognitive coping skills is the problem-solving sequence described earlier (D'Zurilla, 1986). In assessment, the therapist determines the patterns of problem-solving of each of the patients by means of the social problem-solving inventory (D'Zurilla & Nezu, 1988). Simulated problems can also be presented to the group for the members' solutions. The therapist can observe the process. Those who are either impulsive or chaotic problem-solvers would profit from being able to approach problem situations in a careful, step-by-step, analytic, and planful way.

Self-management refers to those cognitive coping skills by which patients control their own environment as a means of controlling their own behavior. Procedures such as the use of environmental cues, self-monitoring, self-instruction, self-modeling, self-evaluation, and self-reinforcement fall under this rubric. These are used in changing patterns of smoking, drug and alcohol abuse, studying, and other problems of self-control, which are targets of change or the themes of many groups in CBGT. As part of assessment the therapist ascertains the degree to which these self-management skills are present and the target behaviors in which the self-management skills can be directed primarily by means of patient self-report and situational analysis. These self-management skills, if learned, represent a set of strategies that the patient can utilize even when only limited external support is available.

Among the most common behavioral coping skills are social skills, a set of learned performance behaviors that relate an individual to others. These include such behaviors as responding to criticism, techniques of dealing with other people (family, friends, colleagues, strangers) in stressful situations, asking for help when needed, disagreeing constructively. They may even be more specific such as giving appropriate eye contact in conversations or smiling occasionally. These social behaviors are often essential for effective social fuctioning and can be readily taught in the group. Social skill inventories (e.g., Gambrill & Richey, 1973) and role-play tests (Magen & Rose, 1998) are commonly used to assess patient skills in this area.

Recreational and leisure time skills may also be regarded as behavioral coping skills. The extent of these interests are explored in assessment to determine whether they should be amplified or modified. Although some are social in nature, they may be regarded as a separate category for coping with general life stress. Information about these skills and interests are obtained in a group exercise in which the members interview each other in pairs about their interests and leisure time activities and then each reports his or her partner's interests and skills to the group.

Because therapy does not go on forever, patients will have to learn to make use of their social network more adequately. A number of social network surveys have been developed which the patients fill in and ascertain the relative helpfulness and limitations of the various social units of which they are a part (see e.g., Rose, 1998b, p. 329, for an example). In the group they share the results of the survey with other members.

Numerous other noninteractive coping skills can be explored as part of assessment such as the patients's ability to manage his or her time, or to relax or mediate during stressful situations. Skills in relaxation can be readily observed as they are taught and tried out in the group. Relaxation is frequently used as part of most cognitive-behavioral programs. In most cases, coping skills and specific behavioral targets are intertwined.

One cannot learn coping skills in a vacuum. One must identify the specific situations with which the individual must learn to cope. To this end the group members are taught to identify and define their unique problematic situations. The therapist first provides models of such situations, which the members discuss in terms of the criteria for formulating troublesome situations they have thus far had trouble dealing with. For example, in a group of men working on reducing the frequency of drinking behavior, an example of a situation in which a coping response was required was as follows:

> A friend of yours stops you after work. He urges you to have drink with him. He notes that several other old friends will be there. You have refused and then he says, "what kind of friend are you, if you can't have a drink with your old buddies."

A group of patients who have problems managing their stress are presented with the following example of a situation that might increase stress and which they will analyze as a group:

> Your car has just been ticketed. You are only eight minutes late for your meter. You really rushed to be back on time. You tell yourself it isn't fair. You know people who are hours late and don't get parking tickets. You feel the tension rising in your stomach.

An example used for a group of men who batter is the following:

> You get home right on time. You've had a couple of drinks, nothing much, you feel, and your wife says she smells alcohol on your breath, you feel anger rising, your head hurts, you say to yourself she can't talk to me that way. If she loves you, you think, she won't nag me. It's my life, I'll drink what I want.

The criteria for a situation that readily lends itself to examination are that the situation is important to the patient and likely to occur again, that it is specific as to time and place and the people involved, and that it represents a situation the patient might have difficulty in dealing with. After discussion of the application of these principles to the model situations, as an extragroup task it is suggested that each person develop one or more such situations which would be presented at the following session in the group in terms of how well each situation meets the criteria. After working with a group for a while, the therapist can put together a role-play test consisting of a wide variety of such situations (see e.g., Magen & Rose, 1998) to ascertain the social skills needed to deal with social situations the patients with a common problem area encounter. The group therapist develops a set of predetermined or "canned" situations for those members who cannot develop one for themselves. An exercise is used to train the members in defining relevant and useful situations. In this exercise a number of models of situations are presented and the members analyze whether the criteria for "useful" situations are met.

As part of assessment and to determine the progress of treatment, data on patient behavior and the resolution of problems are usually systematically collected before, throughout, and following therapy, and several weeks or months after therapy. In order to understand patients' reponse session by session to the program as a whole, a postsession questionnaire is filled out by all the patients and the therapist at the end of each session (see Table 1). In summary, some of the methods of collecting data mentioned above include diaries, personality inventories and checklists, role-play tests, sociometric tests, self-observation, direct observations of the group or of individuals when not in the group, postsession questionnaires, and interviews. (Each of these are discussed in more detail in Rose, 1989, pp. 109–136 for adults, and Rose, 1998, pp. 130–151 for adolescents.) The more structured methods permit evaluation of outcome, one of the purposes of assessment.

Based on the initial data collected in the first part of assessment, goals are eventually established together with the patient. These goals are usually in terms of the specific target behaviors and cognitions that the patients need to achieve by the end of treatment and the coping behaviors required to deal with the problem situations. Knowing each other well because of their intense interaction, the group members provide each other with ideas as to goals each might pursue and feedback as to the formulation of the goals, the importance of the goals, and the degree to which these goals are realistic. Goals may be either behavioral, affective, and/or cognitive change.

Some examples of common treatment goals that people have worked towards in these groups are:

1. (For the depressed patient) By the end of treatment, I will participate in at least two social activities every week with friends or family members. I will also identify any self-defeating thoughts I make and will change each into a coping thought. On my self-monitoring card, I will score an average of 5 or lower on the 10 point depression scale.
2. (For the angry and abusive male) By the end of treatment when I begin to feel angry, I will take a deep breath and let it out slowly and remind myself that I can destroy my marriage if I give way to it. When I experience the first signs of anger with my

> wife, I will excuse myself from the situation and walk away. I will also increase the number of compliments I make to my wife to a minimum of once a day.

The criteria for effective goal formulation are that the goal is important to the individual, that a time frame be provided (e.g., by the end of treatment or by next month), that the goal be sufficiently specific that the patient knows when he or she has achieved it, and that the goal is realistic. If necessary, subgoals may also be formulated which are even more concrete.

The patients are trained in goal formulation by means of an exercise in which the model goals such as those above are provided, the above criteria for effective goals listed, simulated goals are presented and these are corrected in group discussion. Then the members formulate their own goals which are evaluated by the group in terms of how well the goals meet the above criteria. Once goals are formulated, an additional means of measurement, goal attainment scaling, can be used to ascertain progress towards goals (see Cardillo, 1994). The goal attainment scales are developed in the group with the members helping each other. Following the formulation of goals, group programs and interventions can be planned which facilitate the achievement of these goals.

6.15.3.4 Intervention

Based on the goals, intervention activities change or maintenance or decisionmaking strategies are selected. The patients are oriented to these procedures, and with their concurrence, the strategies are applied. Specific strategies are selected which have empirical support as well as a relationship to the goals.

In order to develop these and specific behavioral and coping skills, usually no one intervention technique is sufficient. A number of methods of teaching patients necessary specific skills include problem-solving, modeling (overt and covert), rehearsal, coaching, cognitive-restructuring, rational-emotive techniques, self-instructional training, reinforcement and stimulus control, sociorecreational, relaxation training, and small-group techniques. In CBIGT most of these methods with special emphasis on the group are combined into one integrated approach. A method is selected for inclusion preferably if it has some independent empirical foundation and some relationship to the above mentioned targets. In the following sections, most of these methods will be reviewed in terms of their contribution to the total approach.

6.15.3.5 Generalization

Generalization, a concern of all therapies, refers to the process of transferring what the patient has learned in the group to the outside world and maintaining what he or she has learned beyond the end of therapy. The most fundamental principle of generalization is that it rarely occurs without taking steps to see that it occurs (Stokes & Baer, 1977). One of the major strategies in CBIGT for transferring learning from the group to other situations involves the use of extragroup tasks, described above, which are used in almost every session.

The patients are prepared by modeling and rehearsal on how to deal with persons unsympathetic to their changes. Former patients are sometimes brought in to discuss the possibilities of setbacks and how they might be handled. Possible self-referral sources are discussed, such as a counselor or a local clinic or health service. Finally, as part of this phase, a follow-up or "booster" session would be held two or three months following therapy.

The members are taught the general principles of what they practice specifically. For example, they learn the general steps for problem-solving. They learn the principles of how anxiety and stress is in part a function of how we evaluate situations. They learn the principle that if one practices a given behavior it is more likely that they can learn that behavior. In CBIGT one goes from the specific exercise and experience to learning the general principles behind them.

Members are finally prepared for termination by getting them to develop a plan for how they intend to apply what they have learned in the group when the group ends, and by designing activities appropriate to practicing their newly learned skills. These plans often contain such actions as joining a nontherapeutic group, reading a self-help book, practicing relaxation on a regular basis, meeting with a group member to talk about the principles learned in the group, and meeting again for a booster session.

In order to diminish the intensity of the relationships of the members with each other and with the group therapist as the group approaches termination, the therapist encourages members to establish relationships outside of the group and to become involved in extragroup activities such as family activities, bowling leagues, bridge clubs, dancing lessons, and social organizations. Furthermore, relationships with nongroup members are encouraged. These new activities and social relationship become the focus of the later sessions in CBIGT. Extragroup tasks become less structured but more extensive. Preparation is largely in the hands of the patient. Monitoring is less strict. Social, recreational, and other cohesion-building activities are kept to a minimum in the group. Many of the leadership functions are performed by group members (see Table 2).

6.15.4 INTERVENTION STRATEGIES USED IN CBIGT

The most commn intervention strategies used in CBIGT are systematic problem-solving, the modeling sequence, cognitive change procedures, relaxation, reinforcement and stimulus control, and small group procedures.

6.15.4.1 Systematic Problem-solving

Systematic problem-solving is a central method to CBIGT insofaras patients bring problematic situations of concern to the group and the group under the guidance of the therapist attempts to help them find solutions to those problems. It is systematic insofaras the members follow (or deviate by plan from) specified steps. The steps characteristic of the problem-solving process include orienting the members to the basic assumptions of problem-solving, defining the problem, generating alternative solutions, selecting the best set of solutions, planning and preparing for implementation, implementing the solution, and evaluating the outcome (except for "preparation for implementation" which has been added, these steps are taken from D'Zurilla, 1986). Many of the steps of problem-solving can be classified other than as intervention. For example, orientation to problem-solving is an orientation activity, defining the problem is clearly a part of assessment, implementation through extragroup tasks is part of the generalization of change, and the other steps are intervention activities.

Problem-solving is not only a general paradigm. It can be identified as a set of coping skills to be learned in their own right to replace impetuous or uninformed problem-solving. In using the problem-solving method to find more effective ways of copying with the many problems of concern to group members, patients learn the skills involved in carrying out the general problem-solving paradigm. Such a set of procedures can be effectively taught in groups since the general paradigm is repeated frequently in the course of therapy not only dealing with individual problems but also in dealing with group problems should they arise. Moreover, once learned, it can be used by patients to deal with problems long after the group has ended.

Within the framework of problem-solving, a number of other cognitive and behavioral procedures are used to prepare the group members to impliment the solutions they have agreed to. Each of these have their own empirical foundation. One of the most important is the modeling sequence.

6.15.4.2 The Modeling Sequence

This sequence is designed to teach specific interactive behaviors for coping with various problems situations, and includes such techniques as overt modeling, behavior rehearsal, coaching, and group feedback. Modeling refers to learning that occurs through the observation of a model who might be the group therapist, another member of the group, someone in the patient's environment, or an admired person on stage, on screen, in novels, or in public life. Modeling may be role-played in the group or it may be observed directly in real life. Modeling is specifically used to demonstrate how a situation problematic to one or more patients in the group may be handled effectively. Behavioral rehearsal is a role-play technique in which a patient with a given problem situation practices new, more effective ways of handling that situation. Coaching refers to instructions, verbal or physical cues given to the patient when she or he is modeling or rehearsing a set of behaviors in a given situation.

Group feedback is the verbal evaluation from others as to how effectively the patient role-played or modeled. Following the modeling sequence, the patient prepares for and carries out extragroup tasks to practice the newly learned coping skill in the real world.

> Following the situational analysis of the situation calling for a refusal of drink when offered (see example above), the therapist asks the group members for possible responses to the one of agreeing with the friend and going with him which is what the patient, Pete, had done in the original event. Based on the suggestions of his fellow patients, Pete decided that he would like to refuse clearly and in a matter-of-fact tone of voice, reminding his friend that he (Pete) was on the wagon and was working hard to stay there and he would appreciate whatever help his friend could give him. Pete would repeat the statement if pressured further. The therapist set the scene outside a bar, and then modeled the situation with one of the other group members acting as the friend. Then Pete, who felt that one demonstration was enough, played himself and his friend was played by the same person as in the first role play. When it was finished the therapist asked the other patients to tell Pete what he did well and then what he might consider doing differently. The members responded that Pete made an impressive statement and didn't argue. They suggested that he might consider giving better eye contact and speaking in

Table 2 Group development in a structured group.

Group phase	*Therapist behavior*	*Group processes*
Orientation phase	Orients members to theory and approach Ascertains levels of motivation Encourages broad participation Orients members to each other Introduces rules Promotes protherapeutic norms	Factual communication, limited self-disclosure High mutual anxiety Feedback is limited and polite Norms loosely established Leadership functions primarily controlled by therapist
Preliminary work phase	Stimulates moderate self-disclosure Examines problem situations Extragroup tasks introduced Trains in effective feedback Teaches basic concepts Initiates brief role-plays	Weak subgroups begin to form Increase somewhat in cohesion Members focus attention on therapist Feedback is descriptive and positive Distribution of participation broadens
Deterioration or conflict phase	Examines nonproductive activities Group processes becomes more flexible and empathic Begins to look at consequences of present behavior Initiates discussion of group problems Introduces concept of cognitive distortions Introduces group problem-solving	Homework completion rate drops Feedback is more negative Anger and withdrawal begin to intensify Cohesion begins to weaken Roles and norms are challenged by some members
Resolution phase	Assists members to assume responsibility for therapy Encourages leadership from members Deals with complex situations	Feedback to each other more constructive Cohesiveness decreases slightly Group engages in systematic problem-solving Distribution of participation increases broadly Interaction more task oriented New protherapeutic norms Higher levels of cohesion
Secondary work	Therapist reduces own activity Reduces frequency of reinforcement Encourages members to work on complex problems Interaction highly task oriented Rate of homework completion high	Members assume major phase leadership functions Significant self-disclosure to each other Cohesion decreases slightly Rate of homework completion high
Termination phase	Points to principles of generalization Prepares for termination Increases own activity slightly Summarizes progress Helps individuals to plan post-therapy activity	Group is more spontaneous Cohesion diminishes, focuses on extragroup social units Group focuses on future actions

> a more matter-of-fact tone of voice. Pete rehearsed one more time, trying to incorporate the suggestions with the "friend" in the role play being much more insistent.

The therapist is the director of the role-play. He or she coaches significant others and the target person when necessary. He or she stops the role-play before it goes on too long or if the person cannot handle the situation. He or she instructs the observers as to what they should observe. He or she makes sure the tempo is reasonable. He or she makes sure that the role-play remains task oriented. Modeling is an excellent group procedure because of the presence of many potential models and rich source of feedback, and the opportunity for client leadership if these characteristics are taken advantage of.

6.15.4.3 Cognitive Change Methods

Cognitive change methods refer to the steps taken to train the patient in more effective ways of thinking about or evaluating him or herself as the patient responds in specific problematic situations. In groups many different cognitive procedures are used, often in combination with each other and with other types of procedures such as the modeling sequence. It is assumed that in a given set of circumstances cognitions in part mediate overt behavioral and affective responses. These cognitions include how one values oneself and one's action and how one specifically thinks in or evaluates a given situation. In CBIGT the most commonly used cognitive procedures are cognitive restructuring (Beck, 1976), which includes rational emotive techniques (Ellis, 1973), and self-instructional training (Meichenbaum, 1977).

6.15.4.3.1 Cognitive restructuring

Cognitive restructuring is characterized by two sets of procedures. First, one set of procedures is to identify the distorted patterns of thinking and/or dysfunctional schemata (Beck, 1976) which interfere with social functioning or create intensive emotions. Second, a set of methods are used to replace such distorted or dysfunctional thinking with self-statements that facilitate effective coping with day-to-day life events and reduce anxiety and stress. In the first set of procedures the patients are trained to identify cognitive distortions in case examples or group exercises and to label them into such categories as absolutizing, catastrophizing, mind reading, selective perception, or prophesizing (Beck, 1976). In one exercise the group members are given a list of self-statements which represent both cognitive distortions and coping statements. They are asked to identify independently to which category each statement belongs, and if a distortion, to identify the nature of that distortion and how it might interfere with social functioning and the eliciting of strong emotions. In the group the members exchange their ideas until each person has a clear picture of what a cognitive distortion is and why a given statement is a cognitive distortion.

Later using the theoretical framework they have learned, they are better able to identify their own unique patterns of cognitive distortions, dysfunctional thinking, or illogical expectations and those of their peers. Continuing with the above exercise the clients are asked to identify one statement they are likely to make which they might be identified as a cognitive distortion. To help each other in the process of identification of each person's distorted thinking, the other group members are taught to "rub in" the errors in each person's thinking through logical disputation and analysis. Supportive evidence is also sought through interviewing by the other group members either to invalidate or validate the assumptions of each client. In addition, as members relate ongoing problem situations to the group, they are asked to note their thinking in these situations and to identify and ask the peers to identify any cognitive distortions.

Once the distorted thinking is identified and labeled, each patient, assisted by the other group members, is asked to replace the distortions with coping statements. Group exercises are used to facilitate this replacement in which the patients first correct the list of "canned" statements of distorted or dysfunctional statements. To facilitate this process, a list of coping statements is presented as points-of-departure. For example, "if I take one step at time I can handle this," or "I should remind myself to take a deep breath and relax," or "if I make a mistake it's not so terrible; nobody is perfect."

Once the members become skilled in replacing cognitive distortions with coping statements on simulated examples, they can begin with the help of the group to replace distorted thoughts of their own with coping statements. If they have difficulty the group can provide each other with corrective information or they can "brainstorm" alternate ways of thinking about a given situation which might help them to cope with the situation.

Finally, the members assign each other tasks to perform outside of the group to try out and self-monitor their use of coping self-statements to replace cognitive distortions. At a subsequent session each patient reports back his or her observations to the group.

6.15.4.3.2 Self-instructional training

In self-instructional training, the members are taught first in the face of a problematic or stress-inducing series of situations to utilize functional self-statements at each step of the series. This process consists of step-by-step verbalizations concerning the problem definition ("What's wrong with the way I'm thinking about this?"), problem focus ("What can I do about it?"), focusing of attention ("I should think about how that will get me in trouble."), coping statements ("If I keep relaxing I won't blow it!"), and self-reinforcement ("Wow! I did it! See, I can do it!"). In groups, the members are trained in the method first by providing the members with a model. Examples of situations in which self-instructional training would be appropriate are the following: (i) a situation in which a person is unfairly critizing the patient and escalates the criticism over time; (ii) a situation in which the patient is being persistently hassled to do something she does not want to do; and (iii) a situation in which a person must make a presentation to colleagues and others of which he has little experience. If a given member identifies such a situation, the members brainstorm coping self-statements the given patient might make in the several steps involved in learning to cope with the situation. A group member models the statements (cognitive modeling) for the given patient who then practices the same statement (cognitive rehearsal). The given patient is assigned the task of self-monitoring how he or she handles the given situation should it occur, and reports his or her experience back to the group. Often this method is combined with social skill training.

Other methods with cognitive as well as behavioral elements used in groups are thought stopping in the face of persistent recurring thoughts, systematic desensitization or exposure methods in the case of phobias, and guided imagery. Gradual exposure methods have been used in the treatment of agoraphobia (Hand, Lamontagne, & Marks, 1974) and obsessive-compulsive disorder (Fals-Stewart et al., 1993) with positive results. In the treatment of agoraphobia the group members accompanied each other to face the feared setting together. The group served as support and encouragement for each other. Later the members accompany one person at a distance and eventually each patient faces the feared situation alone.

In the group treatment of obsessive-compulsive disorder (OCD), Fals-Stewart et al. (1993) used both exposure to the feared object (e.g., dirty materials, garbage cans, etc.) and response prevention (e.g., by preventing the individual from washing their hands for at least an hour after exposure to a contaminant). Where *in vivo* exposure was not feasible, imaginal flooding was used. This combination seemed to be effective in alleviating OCD symptoms of patients in groups as well as in individual therapy. The groups are used effectively because of the multiple modeling effect. Also members can help plan each other's hierarchy of anxiety-provoking activities with which they would expect to be confronted in the near future.

6.15.4.4 Relaxation Methods

These are strategies for helping patients to cope with strong emotional responses such as anger, stress, or depression. Thus, relaxation training is an intervention and the skill in relaxation is a coping target in its own right. The training involves teaching patients a modified version of the alternate tension and relaxation technique (developed by Jacobsen, 1978, and adapted by Bernstein & Borkovec, 1973) and then later fading the tension phases. Various alternatives uniquely suited to various populations are also taught. Modest research support for the use of relaxation procedures in reducing anxiety and stress is to be found in studies by Stovya (1977) and Lyles, Burish, Korzely, and Oldham (1982). However, Heide and Borkovec (1983) warn that for a few persons relaxation may increase anxiety. In groups the members are taught the procedures by the therapist modeling the procedure then by having them practice the procedures a few muscle groups at a time. Once the therapist has relaxed the entire group together, in order to make use of the group, the members then go through the same procedures with each other in pairs. The therapist prompts the "teachers" and monitors the process and is available if someone gets stuck. This affords each member the opportunity to be both teacher as well as learner. The members are given tapes and encouraged to practice the relaxation out of the group, if possible with a "buddy" so that they can monitor each other's practice. In addition, meditation (Carington, 1978) and diaphragmatic breathing in some groups are taught as alternatives to deep muscle relaxation.

6.15.4.5 Reinforcement and Stimulus Control

These are not central methods in most applications of CBIGT except in parent training groups where the parents are taught to modify antecedent conditions and consequences with their children. Reinforcement is derived from operant theory and involves the target person performing a target behavior followed by a reinforcing event (positive reinforcement) or the withdrawal of an aversive stimulus (negative reinforcement). Both forms of reinforcement increase the probability that the target behavior will increase under similar conditions in the future. Stimulus control involves procedures in which the immediate conditions which lead to or are parallel with a given behavior are changed to create conditions more amenable to the performance of a desired behavior. Creating conditions in the group through subgrouping as a means of getting broad participation is an example of modifying the stimulus conditions. In groups patients receive many kinds of reinforcement for the performance of prosocial group behavior and the completion of extra-group tasks. With adults, this reinforcement takes the form of praise by the group therapist or other group members. Occasionally it takes the form of smiles, applause, approving nods, and delighted laughter. Also reinforcement is an effective communication skill in its own right if carried out appropriately. Finally, high levels of mutual reinforcement have been shown to to increase the cohesion of therapy groups (Goldstein, Heller, & Sechrest, 1966). For these reasons every effort is made to include as much reinforcement as possible in the early sessions. Reinforcers can also be withheld in response to undesirable behaviors. This is referred to as extinction and is an occasional response in groups when someone is frequently off-task or complains a great deal. Extinction is difficult to perform in groups since it requires the cooperation and prior agreement of all group members along with the therapist.

6.15.4.6 Small-group Procedures

Because CBIGT is also a small-group approach, it is possible to take advantage of the multiple interaction to enhance the effectiveness of the intervention and assessment procedures described earlier and to provide entirely new ones. Since most group therapies make use of some of these techniques, only a few are illustrated in terms of their unique application in CBIGT. These include role-playing, the buddy system, subgrouping, leadership delegation, and group exercises. (These and other group procedures commonly used in CBIGT are described in detail by Rose, 1989, as they apply to adults and Rose, 1998a, as they apply to children and adolescents.)

6.15.4.6.1 Role-playing

Role-playing is a set of procedures that has several purposes in CBIGT. First it is used to demonstrate or model behaviors targeted in problem-solving and for the patient to practice (behaviorally rehearse) them before trying them out in the real world as part of the modeling sequence discussed earlier. It is highly focused and followed by highly specific feedback. Role-playing may also used for assessment by having a patient role-play a problem situation as much as possible as it originally occurred. A set of situations may also be presented to the patients who role-play their responses. It is also used to teach specific therapy skills such as providing constructive feedback and receiving critical feedback, and in generalization training to practice preparing for an unsympathetic environment or the eventuality of setbacks. When using role-playing, practitioners have found it useful to encourage physical movement (knocking at and opening imagined doors, sitting and standing when appropriate), separate the players clearly from the observers, give the observers a clear observational task, and to keep the role-plays brief at least in the beginning. Where patients are reluctant to participate, the therapist will model role-playing with colleagues, write out scripts, and let members express their thoughts with "I would say ... " before having them actually act it out. Usually in groups there are some members who are willing to try it out first and who consequently serve as models for the others.

6.15.4.6.2 Subgrouping

Subgrouping is a simple procedure of working in pairs, triads, or other sized subgroups as a means of increasing interaction among the members and providing them an opportunity to work without the constant oversight of the therapist. Many of the group exercises are performed in subgroups. Subgrouping also creates an opportunity to practice leadership skills. Care is taken to assign subgroups with various compositions in order to avoid "clique" formation which might work against the pursuit of treatment goals. In working with subgroups, the therapist must give them clear assignments, the results of which they report back to the larger groups. He or she must also carefully monitor the activities of the subgroups to make sure they are working on the given tasks.

6.15.4.6.3 Buddy system

The buddy system is a special subgrouping procedure for patients to work together outside of the group (see O'Donnell, Lydgate, & Fo, 1979, for a review of the research with children). In CBIGT the buddy system is especially useful in facilitating completion of the group tasks. Buddies check with each other on their respective progress and reinforce each other for small successes. In addition to the advantages mentioned above, it contributes to the transfer of learning within the group to situations outside of the group.

6.15.4.6.4 Group exercises

Group exercises refer to the use of structured interactive activities as ways of teaching patients the skills which mediate the achievement of therapeutic goals. For example, an introduction exercise is used in which patients interview at least two patients in the group and introduce them to the others. Another exercise is one in which the patients study a case and discuss how each of them is different from the person in that case. In stress groups an exercise is used in which members identify their own unique stress response (see Rose, 1998, for a list and description of commonly used exercises, most of which can be used with adults as well as children). Often the exercises are performed in part in subgroups of varying sizes. Each exercise has a rationale, a stated purpose, and a set of instructions for individuals and for the group as whole. In one particular application of CBIGT, exercises are used in every session. The exercises serve to provide variation in program, enhance interest and cohesion, and create opportunities for broad participation.

6.15.4.6.5 Group feedback

Group feedback is another group technique that plays an important role in group therapy. Members are constantly giving each other feedback as to what they do well and what they might consider doing differently. In CBIGT the patients are trained in how to give feedback in such a way as to maximize its positive reception. The criteria which the participants are trained (in exercises) to use are to give positive feedback first, describe what was done in specific terms, and use an I statement. In giving critical feedback the members are asked to affix the word, "what I might do differently is ..." or "one thing you might consider doing differently is ..." In order to protect the recipient of feedback, he or she can stop feedback any time he or she chooses. Even with these protections the therapist must be careful to monitor feedback to make sure that no one is being devastated by what he or she hears. Usually the norms of giving helpful feedback are quickly established and the group members correct inappropriate feedback whenever it should occur. The group members in contrast with the individual therapist provide a wide range of diverse observations and feedback. The danger of multiple comments being too destructive or aversive can be limited by training the members receiving and giving feedback and by careful monitoring by the group therapist.

6.15.4.7 Identifying and Resolving Group Problems

In all groups one can observe a number of group problems. These can be defined as an intragroup interactive event (or series of events) or a product of interactive events which interfere with effective member task performance or goal attainment. The responsibility for achieving a change in group process cannot usually be linked to a change in behavior of any one member or the group therapist, but to interactive changes among all or most of the members and the therapist. Several problems in particular stand out such as when group cohesion is too low, when the communication pattern primarily directly from members to the therapist and not to each other, when self-disclosure is too low, when some members dominate the interaction while others are virtually excluded, when antitherapeutic norms exist such as a pattern of lateness, and where members are frequently off-task. In general, most of these group problems are avoided by careful treatment programming. Occasionally when a group problem persists, it is necessary to use systematic problem-solving.

The therapist points out the problem as he or she experiences it and checks with the group if they perceive it. Often the therapist can back up his or her perception by the results on the postsession questionnaire or other ongoing measurement procedure. If in discussing the problem, blame is laid at the feet of the therapist, one member, or one subgroup, the therapist points out that the problem cannot exist without the shared contribution of all members and the therapist. It requires a change in behavior or attitude of everyone. If the group agrees, the members are asked to brainstorm what the group can do, what each member him- or herself can do, and what the therapist can do to ameliorate the problem. Then the group uses the ideas to negotiate a group plan and a therapist plan and each person commits him- or herself to an individual plan all of which are found in the following example.

> In a hospital group of patients with borderline personality disorders, the therapist noted that everyone seemed to be addressing all their questions to her and not to each other, in spite of the fact that many of them knew the answers better than the therapist. The co-therapist had been noting the direction of all interaction at the past session and provided the group this information. The group members agreed, stating that it was easier, somehow, to do that, and besides she had the most power. The therapist pointed out that eventually they would have to depend on their own resources and those of their peers, and this was a good opportunity to practice solving a problem. Since the group members agreed with her assessment, she suggested that everyone write down one idea as to what the group could do differently, what the therapist could do differently, and what each of them could do differently. An extensive list for each category was generated, and after an evaluation, the group selected for the group that whenever a question is asked, everyone would write down what

> they each thought was the answer. Then the person asking the question would ask the others what they had written. They agreed that the therapist would throw back to the group any question directed to her and remind them of the agreement. The individual plans included relaxing before the session and before answering a question, looking at other members instead of the therapists, and listening more carefully to each question asked by writing down the question.

6.15.4.8 Phases of Group Development

Many of these group problems are a function of the phase of group development in which the group finds itself. Group development refers to the ways in which norms, roles, cohesion, communication patterns, subgroups, and leadership shift over time. In that sense group development is a kind of metaprocess. Common elements seem to run through most paradigms of group development (see e.g., Corey & Corey, 1997; Forsyth, 1990; Garvin, 1987, pp. 110–111; Sarri & Galinsky, 1985; Tuckman, 1965), which suggest that some phenomena are at least in part a function of time. It is useful for group therapists to be aware of group process insofaras the phase of therapy is one of many conditions which may contribute to the appearance of certain behaviors viewed as obstructionist or constructive such as one might experience in the conflict phase.

In Table 2 these often overlapping phases are differentiated into the phase of development, the therapist activity, and the observable group phenomena.

6.15.4.9 Integrating Diverse Intervention Strategies in CBIGT

In the following example the way in which various intervention strategies are developed into an integrated treatment package in CBIGT are examined.

> In the fourth session of a stress management group the therapist reviewed the postsession data from the previous week. He noted that satisfaction and a feeling of self-control of the activities of the group had showed a lot of improvement over the previous session and the members agreed that that was a good sign. Then the therapist asked each member to review what he or she had done on the extragroup tasks during the week. Applause and cheers greeted those who completely or partially succeeded.
>
> A group exercise was used to train all the members in correcting the cognitive distortions that they had identified the previous week in the first part of the exercise. In this exercise each person eventually identified one distortion that each usually made. Following the exercise, each member brought in a stressful situation he or she had encountered the previous week and had recorded in their diaries. For example, Laura told about a commonly occurring situation in which she felt upset by the half joking way in which her boss implies criticism of her in front of others but never states it. She always felt anxious at work and constantly afraid he would criticize her at any time. The other members by asking questions helped to spell out the details of the situation and to relate it to other situations in which she is also often quite anxious. They also examined her thoughts in these situations. In each situation, the group suggested how her self-defeating statements, "I can't stand being criticised," "If I'm criticized, I must be an awful person" seem to keep her in a state of constant anxiety and she agreed that something must be done about these cognitions and some action with respect to her boss was called for. Based on suggestions generated through "brainstorming" from the group, she decided to do two things differently. First, she would let her boss know that she was dissatisfied (while reminding herself that she was a highly regarded employee and she was willing to risk any potential fall-out) with his public suggestion of criticism; if he had any criticism she would like to hear it explicitly stated in private. Whenever she began to feel negative about herself, she would take a deep breathe and relax. In order to prepare Laura to carry out the solution, several members of the group demonstrated in a role play how she might act with her boss, and then she rehearsed what she would actually say first to herself and then aloud to her boss. Then several members demonstrated how, when confronted with implied criticism, what she might think to herself and say aloud to her boss. Laura also rehearsed her thoughts and her actions until she indicated she was comfortable with the way she handled them. Most of the other members handled a similar stress inducing situation with emphasis on the cognitions that prevented them from dealing with them.
>
> Towards the close of the session, all the members designed with a partner their new extragroup task and announced it to the group. For example, Laura reported that she would make an appointment with her boss and then carry out the plan developed earlier in the session. She would also monitor her self put-downs and her self-praise statements throughout the following week (which she has been working on for several weeks) and practice relaxation at least four times for 15 minutes each time. After the others also reported a plan for their extragroup task, they practiced relaxation (all had problems with handling strong emotions) in pairs. The session was closed by filling in the postsession questionnaire.

Although sessions vary considerably, the above session is typical insofaras previous extragroup tasks are monitored, the results of the postsession questionnaire are reviewed and evaluated, a group exercise is carried out, problematic situations are presented by most of the members of the group, alternative responses to those situations are generated, cognitive and overt modeling of the alternative responses takes place, the members practice cognitive and behavioral alternatives for which they receive group feedback, cognitive distortions the client may have had in relation to the situation are considered, relaxation is practiced, and extra-group tasks are planned. The group was used in many ways: the use of role-playing, subgroups, the generation of ideas, group exercise, group feedback, and the structuring of broad participation. All were integrated into a coherent and fast-moving session.

6.15.5 SUMMARY AND CONCLUSION

Some of the research supporting the use of CBGT with various populations has been reviewed. It appears that group therapy is as effective as individual therapy and more efficient. It is also more effective than doing nothing and several other alternative therapies. Follow-up information is either limited or reveals little maintenance. Most of the research on CBGT does not report on any use of the group beyond it being the context of treatment. In this chapter the reader has been presented with one type of cognitive-behavioral group therapy in which use is explicitly made of the group. The various assessment, intervention, and generalization strategies employed in CBGT have been presented specifically as they could be uniquely applied in a group and which take advantage of the group context. Specific group interventions are identified. The cornerstone of using the group is maximum involvement of the members in the treatment process both as patient and as cotherapist. Because of the focus on interaction, this particular approach to CBGT has been referred to throughout as cognitive-behavioral interactive group therapy or CBIGT.

It is clear that intense involvement of members in the therapeutic process is costly in time. Much less can be covered in a given number of sessions. According to our clinical observations, failure to become involved often results in a highly didactic quality of therapy, high drop-out rates, and lower levels of learning. More research on these very issues is required before one can be firmly committed to this conclusion.

6.16.1 INTRODUCTION

The array of human problems which has come to be known as the affective disorders offers students of psychopathology an engrossing course of study. The modern conception of this nosologic category encompasses both depression and mania, disorders in which the most basic human drives and desires are altered, in many cases to such a degree that life itself is threatened. Hunger is extinguished, or in some cases excessive. Sleep is severely disrupted. Sexual appetite evaporates or goes out of control. And the desire to live, taken for granted by most people most of the time, can be replaced by the urge to die. Secondary drives and motives suffer as well. Achievement strivings, pride, and a sense of belonging in a social network become distant memories if they are remembered at all, or they are perceived out of proportion to reality.

Nearly all of psychology's philosophical, methodological, and scientific battles have taken place in the field of the affective disorders. Although many of the secrets of the affective disorders have yielded to scientific inquiry, and there is little controversy about the nature and treatment of mania, uncertainties regarding many of the most basic issues in depression remain. Is the distinction between a sad mood and major depression one of degree or of kind? Is depression essentially psychological or biological in nature? To what degree is it caused by genetic factors, and to what degree by environment? Of the environmental influences, is the key factor childhood upbringing, or is it a difficult environment encountered in adulthood? And finally, which are the more effective treatments for depression: biological or psychological ones? The answers to each of these questions are complex, but with the enormous amount of research conducted since the 1960s, the field is moving closer to an integrated understanding of depression and its treatment.

In the last four decades the field has also witnessed several new discoveries and the development of potent treatments for the affective disorders. With the exception of electroconvulsive therapy, none of the treatments used 40 years ago are among those considered effective today. Specific antidepressant medications, as well as targeted psychosocial interventions, have been added to the list of effective treatments. A newly described variant of affective disorder, seasonal affective disorder, has led to the development of light therapy, a treatment that would have been the stuff of science fiction 25 years ago. Advances in genetics have not yet informed our understanding of the biological processes involved in the affective disorders, but we now understand that genes play a substantial part in the development of depression and mania.

Note that brand names given in this chapter refer to the most commonly prescribed brands in the USA. Brand names other than those mentioned here are also used in the USA as well as internationally.

6.16.2 PHENOMENOLOGY

The phenomena that make up affective disorders form classic syndromes in that a wide array of distinctive experiences (symptoms) and behaviors (signs) are found to appear together to form coherent clusters. Though disturbed mood is usually a central feature in a person who is diagnosed with an affective disorder (sadness in depression; euphoria in mania), these symptoms are not required for either diagnosis. Instead, the person must possess a collection of phenomenologically disparate signs and symptoms. The system embedded in the fourth edition of the *Diagnostic and statistical manual of mental disorders* (*DSM-IV*; American Psychiatric Association [APA], 1994) will be used to describe the syndromes of major depression and mania.

6.16.2.1 Phenomenology of Depressive Episodes

Modern diagnostic systems recognize a distinction between short-term emotional upset and a major depressive episode, in part by requiring the presence of the depressive syndrome over a period of time. Two weeks has been chosen as a reasonable if arbitrary cutoff. Moreover, the depressive syndrome is not considered to be present if the signs and symptoms can be accounted for by a normal bereavement reaction, a medical condition, or a reaction to a medication or a drug of abuse. In this way, the depressive syndrome designation is reserved for cases in which the appearance of depressive signs and symptoms is neither normative nor readily explained by gross somatic disturbance.

The *DSM-IV* requires that, for a major depressive episode, either sadness or lack of interest/pleasure be present most of the day, each day. Sadness is usually a reported symptom, but its presence can be inferred from crying spells or from facial expression. Diminished interest in activities can be obtained from the patient's subjective report, or it can be inferred from reduced participation. Markedly reduced interest in sexual activities is common.

The vegetative symptoms, especially sleep and appetite disturbance, are seen by many as the essential indicators of depression. The classic forms of these disturbances entail sleep loss (insomnia) and a decreased appetite (hypophagia), but it is now widely recognized that the reverse, hypersomnia and hyperphagia, are commonly found in persons with the other symptoms of the depressive syndrome. Thus, these reversed vegetative signs are included in the most recent diagnostic systems and assessment tools. Persons whose affective episodes follow a seasonal pattern (see Section 6.16.3.3) are particularly likely to experience these reversed vegetative symptoms.

The motor symptoms of agitation and retardation are especially observed in the more severe forms of the syndrome. Agitation is manifest in pacing or fidgeting, and the experience that it is difficult to sit still. Psychomotor retardation is observed in slowed speech and movements, and is reported as the feeling of moving in slow motion. Depressed patients also report fatigue and reduced energy that cannot be attributed entirely to either sleep deprivation or diminished interest.

Cognitive symptoms are also observed in depression: excessive self-blame or guilt, along with the belief that one is inadequate or unworthy, are nearly always present. Such beliefs can become so unconnected to reality as to be delusional. Extreme pessimism about the future, a state referred to as hopelessness, is also common.

Depressed persons often report great difficulty with concentration and decision-making. Simple acts such as reading the newspaper, following a conversation, or watching television, can become virtually impossible for the severely depressed person. Problems with concentration and decision-making result in part from the distraction caused by persistent worries, but they also reflect cognitive inefficiency, possibly associated with hormonal disturbance (Rubinow, Post, & Savard, 1984).

Depressive disorders also include milder forms, which are nonetheless bothersome enough to warrant attention and treatment, especially when they are experienced over long periods of time. Dysthymic disorder refers to long-lasting episodes of mood disturbance that are not severe enough to qualify as a major depressive episode. For a person to be deemed dysthymic, mild to moderate levels of depressive symptoms need to be experienced most of the day, more days than not, over a two year period (APA, 1994).

6.16.2.2 Phenomenology of Manic Episodes

Modern conceptions of manic syndromes have their roots in the descriptions of manic depressive illness articulated by Kraepelin (1921) in the early part of the twentieth century. These descriptions continue to be some of the most illustrative accounts of the phenomenology of mania.

The central feature of a manic episode is a distinct change in mood. This change can be reflected in either an elevation of mood (elation, euphoria), or in irritability. Elevated mood may be inferred by behaviors such as joking, laughing and singing. Euphoria is not necessarily perceived as problematic by the patient. *DSM-IV* requires that the change in mood lasts for at least one week, or less if the impairment is severe enough to warrant hospitalization. Dysphoria (sad mood) may occur within a manic episode, and there may be frequent changes between elation and depression. Persons with this pattern have been labeled dysphoric manics, or as those having a mixed episode (Post et al., 1989).

Inflated self-esteem and grandiosity are characteristics of mania. The manic person often has an exaggerated sense of achievements and abilities. Grandiosity may also be observed in the manic person's behavior, such as embarking impulsively on ambitious but unrealistic projects, or giving advice on matters about which he or she has little knowledge. The grandiosity may also manifest in delusions, such as a belief that one is a deity or a famous public figure.

Increases in energy are observed in mania. In earlier stages and milder forms of mania, this may manifest in increased goal-directed activities in social or occupational realms, some of which may be successful. In later stages, manic persons may be unable to sit still, and they may initiate many tasks that they are unable to complete because of severe distractibility. The increase in activities may include imprudent involvement in pursuits of pleasure which have high potential for painful or dangerous consequences. Increased sexual drive can lead to impulsive and reckless sexual behavior, such as infidelity or sexual encounters with strangers. Buying sprees that involve expensive, unneeded items, gambling binges, or foolish business investments create financial problems, which can exacerbate subsequent depressive episodes.

Decreased need for sleep is common. Fogarty, Russell, Newman, and Bland (1994) reported reduced sleep as the most frequent symptom in those with a history of mania. The sleep disturbance seen in mania differs from that observed in depression; in mania, the disturbance is related to a marked decrease in perceived need for sleep. Some manic individuals go for days without any sleep, yet they report no fatigue. By contrast, in depression the decreased sleep (insomnia) is unwanted, and the restless sleep that does occur is not experienced as restorative.

The disturbed thought processes of mania are distinct and can be readily observed in the speech of the manic patient. The rate of speech is rapid; interrupting the manic patient can be difficult. Speech is often colorful, and characterized by the use of rhymes, puns, and word associations based on sounds rather than meaning (clang associations). Persons in a manic episode may report that thoughts are racing through their mind. The thought disorder characteristic of mania, which is reflected in the content of speech, is known as "flight of ideas." Speech may be tangential, or there may be frequent, loosely associated shifts from one topic to another. Individuals in a manic episode are characterized by their inability to screen out irrelevant stimuli, both internal (thoughts) and external (sights, sounds). This distractibility can be observed in the quickly shifting speech content and activities of the manic individual. The symptom known as "pressured speech" refers to the forced quality of utterances. It is experienced by the manic person as an inability to slow down or inhibit speech.

Psychotic symptoms such as delusions or hallucinations are present in more than half of manic patients (Silverstone & Hunt, 1992). Delusions in mania tend to be grandiose, but paranoid delusions are not uncommon. Hallucinations are most frequently auditory, and are usually congruent with prevailing mood and themes of grandiosity.

6.16.3 CLASSIFICATION

The heterogeneity of the affective disorders has led to numerous attempts to discern meaningful subcategories. The usual nosologic aims of improving the search for causes and treatments have driven these efforts. The severity of depressive symptoms varies considerably, from mild dysphoria to psychotic forms. Moreover, the observed variation appears to be continuous. Meaningful distinctions have been made, however, with implications for etiology and treatment.

6.16.3.1 Unipolar–Bipolar Distinction

Of the many attempts to divide the affective disorders into meaningful subclassifications, no distinction has proven more fruitful than that between unipolar and bipolar forms. Through the middle part of the twentieth century, Kraepelin's (1921) diagnostic category of "manic-depressive insanity" included all patients who experienced a manic or a depressive episode, whether or not they had experienced both poles of affective disturbance. The use of the term "manic-depressive" is today more a source of confusion, since it implies that one suffering from it would have experienced (or could expect to experience) both mania and depression.

In more modern classification systems this confusion has been eliminated. Separate categories have been recognized for (i) patients who have experienced only depressive episodes—unipolar disorder; and (ii) patients who have experienced both manic and depressive episodes—bipolar disorder. There was some concern that a third category, for patients who experienced only manic episodes, would be needed, but research on the treatments, genetics and clinical courses of these patients has shown that they are best considered bipolar, rather than unipolar manic, despite the absence of a depressive episode. The organization of much of this chapter recognizes the importance of the unipolar–bipolar distinction. Differences between unipolar and bipolar disorders have been found in regard to (i) epidemiologic factors, including gender distributions; (ii) genetics; (iii) psychosocial causes; (iv) course of illness; (v) biologic variables; and (vi) treatments.

Perris (1992) reviewed findings from family studies, twin studies, and adoption studies that together support the claim that unipolar and bipolar forms of affective disorder are, at least to some degree, genetically distinct. In the family studies, unipolar (or bipolar) probands were identified, and their first-degree relatives were assessed for the presence of unipolar or bipolar disorder. The mean morbidity risk for bipolar disorder across seven family studies of unipolar probands was less than 2%, close to the population risk, whereas the risk for unipolar disorder was considerably higher, at 15%. These figures can be contrasted with those obtained in 14 studies of bipolar probands. The mean risk was 9% for bipolar disorder, which is much higher than the population rate. However, the risk for unipolar disorder was rather high also, at 13%. Although some of the unipolar relatives in this last group may have been misdiagnosed—early episodes in bipolar disorder tend to be depressions—clearly the relatives of bipolar patients are at increased risk not only for bipolar disorder, but for the unipolar form of affective pathology as well.

6.16.3.2 Melancholic–Nonmelancholic Distinction

The most enduring subtype within the depressive spectrum has gone by several names, but the use of "melancholic" to refer to the classic presentation of depression has endured through most of the twentieth century. The concept, which has obtained inconsistent support from research findings, is that melancholic (or endogenous) depressions are caused more by biological factors, and should respond better to biological treatments, than their opposite—the so-called exogenous (or nonmelancholic, reactive, or neurotic) depressions.

There is indeed a melancholic symptom pattern that coheres fairly well (Haslam & Beck, 1994), although the presence of endogenous symptoms is also indicative of, and may simply reflect, a more severe form of depression. Melancholic features include: early morning awakening, weight loss, loss of pleasure, and loss of reactivity to usually pleasurable stimuli. By contrast, a nonmelancholic pattern may involve no sleep or appetite disturbance, or a reversed pattern, characterized by excessive sleeping and weight gain. In addition, such individuals often experience a lifting of mood in response to rewarding or pleasurable events in their environment.

Attempts to validate the melancholic–nonmelancholic distinction have produced mixed results. The assumption that melancholic (endogenous) depressions "arise from within," and are therefore not likely to have been preceded by a negative life event, has not generally been confirmed with data (Grove & Andreasen, 1992). Most researchers have found that plausible precipitating events are common in both endogenous and exogenous depressions, although the association may be stronger in melancholia (Brown, Harris, & Hepworth, 1994).

However, the endogenous–exogenous distinction does predict response to biological treatments. Both electroconvulsive therapy and antidepressant medications are more effective for endogenous episodes than for episodes with a reactive symptom pattern (Grove & Andreasen, 1992). The "biological vs. non-biological" connotation of this distinction would receive even more support if the reverse pattern were found for psychosocial interventions. There has been little investigation of this question. Not one large-sample prospective comparison of biological and psychological treatments has been conducted, but results thus far have indicated that psychosocial treatments such as cognitive therapy may not be as effective with melancholic depressions as they are with nonmelancholic depressions (Thase et al., 1996). Finally, biological abnormalities associated with depression, such as the dexamethasone suppression test, are found more often in melancholic than in nonmelancholic depressed patients (APA Task Force on Laboratory Tests in Psychiatry, 1987).

6.16.3.3 Seasonal–Nonseasonal Distinction

Since the 1970s, increased attention has been given to a subtype of affective disturbance that follows an annual pattern—seasonal affective disorder (SAD). An appreciation of this pattern has led to important advances in its treatment, and to an increased understanding of the biological mechanisms that play a role in all depressions. Moreover, the fact that some depressions follow a seasonal pattern has fueled an interest in the evolutionary function that this depressive complex might have served for our ancestors (Whybrow & Bahr, 1988).

The typical annual course for SAD is an onset in mid to late autumn, with either remission of symptoms in early spring, or a period of hypomania or mania followed by a return to normal mood. The symptom pattern found in SAD differs from that found in nonseasonal depressions. The "reversed vegetative symptoms" of hypersomnia (increased sleep) and hyperphagia (increased appetite) are common. In this regard, SAD is similar to another subtype of depression—atypical depression (Lam & Stewart, 1996); however, it differs from atypical depression in important ways. Craving for carbohydrates, especially sweets, is pronounced in SAD, but not in atypical depression. Interpersonal sensitivity and avoidance of rejection are not common in SAD, but they are defining features of atypical depression (Tam et al., 1997). Lethargy and disinterest are especially common in SAD. The signs of SAD are thus akin to those observed in a hibernating animal (Whybrow & Bahr, 1988).

SAD is found predominantly in the higher latitudes, such as in Scandinavian countries or the southern parts of South America. It is nonexistent near the equator, because light and climate conditions vary seasonally in the higher latitudes, but not in the lower. Separate influences of light and temperature have been difficult to distinguish (Molin, Mellerup, Bolwig, Scheike, & Dam, 1996), because they tend to covary. Although it is possible that temperature plays an independent role, it is believed that some aspect of exposure to light is critical for the development of SAD. Whether the critical variable is length of day (i.e., time from light onset to light offset), or total amount of light, has been difficult to determine.

Treatment for SAD involves therapeutic exposure to high intensity light (see Tam, Lam, & Levitt, 1995). Although most research has been conducted on light presented before 8 a.m., the timing of the light treatment may not matter for most patients (Meesters et al., 1993). The spectral properties of the light seem also not to be critical—white, red, green, and blue light all appear to be equally effective. Intensity of light is important, however—2500 lux for one to two hours per day is a well-documented regimen, whereas less intense light (e.g., 500 lux) is not as effective (Tam et al., 1995). Briefer exposure (e.g., 30 minutes) with a higher intensity light (10 000 lux) appears to be as effective as the standard treatment, lending credence to the view that it is the total amount of light that falls on the retina which is critical in the development and treatment of SAD (Terman et al., 1990).

What physiological mechanisms explain how the absence of light can lead to depressive symptoms? How can treatment that involves only the presentation of extra light alleviate SAD? The answer lies in the fact that humans possess a tract of nerves that runs directly from the retina to the hypothalamus, without passing through the visual cortex. Presumably, this nonvisual tract plays a role in the regulation of, for example, mood, appetite, and sleep—functions controlled by the hypothalamus.

6.16.4 ETIOLOGICAL FACTORS

6.16.4.1 Epidemiology

6.16.4.1.1 Epidemiology of unipolar disorder

Depressive disorders occur on a continuum from mild (dysthymic disorder) to very severe (psychotic, melancholic forms), with no clear thresholds marking the transition points. This has made it difficult to study the prevalence of depression across time and across settings, as well as across cultures. Since the 1970s, epidemiological studies have benefited greatly from the development of standardized assessment methods, beginning with the criteria of Feighner et al. (1972) in the USA, and the Present State Examination (Wing, Cooper, & Sartorius, 1974) in the UK. In a review of studies that were conducted prior to the development of these instruments, Boyd and Weissman (1981) reported estimates of lifetime prevalence of unipolar depression that ranged from 3% to 18%. Most researchers now cite the newer Epidemiological Catchment Area study (ECA; Weissman et al., 1988), a large, five-site community survey that employed the Diagnostic Interview Schedule (Robins, Helzer, Ratcliff, & Seyfried, 1982) to determine *DSM-III* (APA, 1980) diagnoses. In the ECA, lifetime prevalence of unipolar (major) depression was estimated at 4.4%. A further 3.2% were found to suffer from the milder, chronic version of depression, dysthymia (Gwirtsman, 1994). A substantially higher estimate of major depression (8%) was obtained in the recent, large Edmonton study (Spaner, Bland, & Newman, 1994), with methods similar to those used in the ECA study. It appears, then, that findings from the earlier studies overestimated the prevalence of unipolar depression. At this point, it would be safe to say that lifetime prevalence of major depression in western societies is in the range of 4–8%. However, this may be changing rapidly.

Indeed, the most disturbing findings to emerge from depression research since the 1970s concern indications that depression rates have been increasing dramatically in industrialized cultures during the twentieth century (Klerman & Weissman, 1989). Klerman and Weissman estimate that the birth cohorts born after World War II incur more risk for depression than cohorts born early in the twentieth century, perhaps by a factor of five or more. The same data suggest that the mean age of onset has been decreasing sharply in the same time period. Whereas the older studies yielded mean age-of-onset figures in the 50s or 60s, recent estimates suggest a mean age of onset in modern industrialized nations in the late 20s. The most dramatic change in age of onset also appears to have occurred in the cohorts born around the time of World War II and later. It is impossible to rule out conclusively all of the potential artifacts in such findings, especially since most of the data rely on respondents' memories and their willingness to report potentially embarrassing feelings and behaviors. However, the phenomenon survives careful scrutiny. For example, the same epidemiologic methods have been applied in nonindustrialized cultures, and no increases in depression rates over time have been observed. Even though Klerman and Weissman's estimate of the increase in rates is almost certainly an overestimate (Fombonne, 1994), there is little doubt that depression is and will continue to be a more common disorder than it was in our great-grandparents' day, when it was a rare disorder.

Despite between-study and between-era differences in rates of depression, a consistent finding is that women experience unipolar depression at about twice the rate of men (Weissman & Klerman, 1985). Several explanations have been advanced to account for the gender difference; it appears that it cannot be explained by a reporting artifact, or by differential willingness to consult mental health professionals. Women have been found to engage in more ruminative, self-reflective thinking when they experience a low mood, whereas men engage more often in distracting activities (Nolen-Hoeksema, 1987). Hormonal differences and differences in the traditional roles adopted by men and women appear also to play a role in the gender discrepancy (Nolen-Hoeksema, 1987; Weissman & Klerman, 1977).

There has been a consistent and surprising lack of association between socioeconomic status and depression in epidemiological investigations (Weissman et al., 1988). Likewise, within Western societies, racial and ethic differences in rates of depression have not been observed. Marital status is associated with depression, however. Married persons who have never divorced have the lowest rates, followed by those who have never married. The highest rates tend to be found for divorced persons, especially those recently divorced. Although the nature of the causal relationships involved is unclear, there is good evidence that the presence of a supportive relationship, such as can be found in a good, stable marriage, acts as a buffer against environmental stressors (Brown & Harris, 1978). Alternatively, the interpersonal adjustment of depressed people is found to be impaired (Barnett & Gotlib, 1988). Thus, a portion of the relation of marital status to depression is undoubtedly due to the damaging effects of depression on intimate relationships, including marriages.

6.16.4.1.2 Epidemiology of bipolar disorder

Bipolar illness is much less common than unipolar depression. In the ECA study, the lifetime prevalence was of bipolar disorder was 1.2% (Weissman et al., 1988). Whereas depression is more common among females than males, gender does not appear to be a significant risk factor for bipolar illness. Results of the ECA study indicate that the prevalence of bipolar illness is nearly equivalent in the two genders, with a female:male ratio of 1.2:1 (Weissman et al., 1988).

The average age of onset of bipolar disorder is 20. About one in four bipolar patients experience their first affective episode prior to age 20 (Goodwin & Jamison, 1990). ECA data (Weissman et al., 1988) indicate that incidence of bipolar affective disorder was highest in the sample of 18–44 year olds (1.4%), and that there were virtually no cases reported in the group aged 65 and over (0.1% incidence).

It is estimated that in just over half of bipolar patients, the illness commences with a manic episode. On average, manic episodes develop within a few days, whereas depressive episodes develop less abruptly, usually within a few weeks. Manic episodes are also shorter in duration than depressive episodes (Keller et al., 1986; Goodwin & Jamison, 1990). Gender differences in the course of the illness have also been examined. Manic episodes were predominant in males with bipolar illness, whereas depressive episodes were more frequent in females (Coryell et al., 1989).

Prior to the advent of effective drug treatments, the average natural duration of a manic episode was about 17 weeks (Wertham, 1928). Since somatic treatments have been available, the average duration of an episode has decreased to 10 weeks (Coryell & Winokur, 1992). Bipolar disorder is a chronic, recurrent illness. Most individuals with this disorder will experience more than one episode during their lifetime (Goodwin & Jamison, 1990). There is evidence that the time from the onset of one episode to the onset of the next (cycle length) decreases for each subsequent episode (Goodwin & Jamison, 1990), and that each affective episode increases the probability of future relapse (Keller, Shapiro, Lavori, & Wolfe, 1982).

It is estimated that 13–20% of bipolar patients are rapid cyclers. Rapid cycling describes a subgroup of bipolar patients who experience more than four affective episodes in a year (Dunner & Fieve, 1974). Females are more likely than males to exhibit rapid cycling (Goodwin & Jamison, 1990). Although rapid cycling is present from the onset of illness in about 20% of cases, the majority (80%) develop rapid cycling later in the course of the illness. The fact that rapid cycling generally develops later in the course of the illness may reflect an underlying pathophysiological mechanism, such as progressive kindling or sensitization (Post, Rubinow, & Ballenger, 1986). Kindling refers to the process whereby alterations in neurotransmitter systems, such as occur in depression or mania, transform the brain so as to make it more vulnerable to dysregulation in the future.

6.16.4.2 Genetics

6.16.4.2.1 Genetics of unipolar disorder

Progress in the behavior genetics of depression has lagged behind that of similar work in schizophrenia. However, there have been enough replications of well-conducted family studies and twin studies to warrant the conclusion that risk for unipolar depression is, at least in part, heritable. From family studies it is estimated that the risk to first-degree relatives of depressive probands is 11–18%, compared to 0.7–7% for relatives of normal controls (Moldin, Reich, & Rice, 1991). The higher figures within each of these ranges more likely correspond to the thresholds employed in modern estimates of population risk cited in the earlier section on epidemiology in this chapter. The main advantage of family studies over other behavior genetic investigations is their large sample sizes (usually in the hundreds). The drawback is that, although findings from family studies can reveal general familial risk, they cannot distinguish genetic from environmental contributions.

Findings from twin studies can help to disentangle genetic from environmental factors. There have been five twin studies completed in which the concordance rates in monozygotic (MZ) twins have been compared to the concordance rates in dizygotic (DZ) twins. The greater the ratio of MZ concordance to DZ concordance, the stronger the evidence for a genetic contribution to depression. In each of the studies (Allen et al., 1974, Kallman, 1953, Slater, 1953 [pooled together in Allen, 1976]; Bertelsen et al., 1977; Torgersen, 1986; all cited in Nurnberger & Gershon, 1992), the MZ concordance was higher than the DZ rate. The MZ:DZ ratios ranged between 2.3:1 and 3.4:1, suggesting a substantial genetic contribution to unipolar depression.

In behavior genetic work, adoption studies are critical because they can help rule out confounds that remain in even the best family and twin studies. Only four adoption studies have been conducted, however, in which unipolar depression was a focus of investigation. Although three of the four studies (Cadoret, 1978; Mendlewicz & Rainer, 1977; Wender et al., 1986) yielded findings consistent with a genetic hypothesis, very small sample sizes (Cadoret) or very low rates of unipolar illness in the sample (Wender et al.) reduce confidence in two of them. Furthermore, Mendlewicz and Rainer did not distinguish unipolar from bipolar adoptees in their study, although they did ascertain the polarity of the biological and adoptive relatives. Finally, von Knorring, Cloninger, Bohman, and Sigvardsson (1983) found no differences in the rates of unipolar depression between biological and adoptive relatives of unipolar adoptees. Surprisingly, these null findings extended to comparisons between the relatives of unipolar adoptees and the relatives of control adoptees, despite a rather robust sample size.

To summarize, the evidence of a genetic contribution to unipolar depression has been inconsistent, and weaker than the evidence for several other mental disorders, including bipolar disorder. McGuffin and Katz (1989) point out that the inconsistencies in findings across genetic investigations of unipolar depression may arise from differences in the definition of depression used in the various investigations. They cite evidence that as one moves from the more severe forms of affective disorder (including bipolar disorder) to the moderate forms, and finally to the milder, or neurotic forms, genetic contribution diminishes, whereas the contributions of both familial (common to all members of a family) and non-shared (unique to the individual) environments increase.

In part due to the difficulty of ascertaining cases of unipolar depression, and because the environmental contribution to risk is substantial, efforts to identify the mode of genetic transmission for unipolar depression, and to identify the specific genes involved, have not been successful (Moldin et al., 1991). It appears that for the time being, biologically oriented researchers will need to focus on the biological markers and treatments for depression, knowing that genes play some role. An understanding of the ways in which genes play their role awaits refinements in the ascertainment of unipolar depression and its subtypes.

6.16.4.2.2 Genetics of bipolar disorder

The primary etiologic understanding of bipolar disorder is that it is transmitted genetically. Belief in the heritability of bipolar disorder is buttressed by findings from family, twin, and adoption studies. More recently, studies of genetic linkage and genetic association have been conducted. These are attempts to identify specific genes that play a part in the pathogenesis of bipolar illness.

Studies of families have consistently shown that the prevalence of affective disorders (both unipolar and bipolar) are higher in the families of patients with bipolar disorder than in families of nonpsychiatric controls. When relative risk factors are calculated (ratio of the risk in relatives of probands to risk in relatives of controls), family studies of bipolar disorder produce relative risk values upwards of 15 for bipolar disorder, and between two and five for unipolar illness (Alda, 1997). Findings from these studies have also suggested that the various forms of affective illness are related in a hierarchical way—relatives of bipolar probands have increased risk for both bipolar and unipolar disorder, whereas relatives of unipolar probands tend only to have increased risk for unipolar illness (Perris, 1992).

Studies of twins have also provided substantial evidence for the heritability of bipolar illness. Bertelsen, Harvald, and Hauge (1977) observed an 80% concordance for bipolar disorder in MZ twins. Overall concordance rates for bipolar disorder are estimated at 57% for MZ twins, as compared to 14% for DZ twins (Alda, 1997). Moreover, the concordance rates of MZ twins reared apart do not differ from those reared together (McGuffin & Katz, 1989).

Results of adoption studies are consistent with family study data (McGuffin & Katz, 1989) Mendlewicz and Rainer (1977) have conducted the largest adoption study of bipolar probands. For biological relatives of bipolar patients who had been adopted away from their biological parents, the risk was similar to that of relatives of bipolars who were not adopted (approximately 25%). Adoptive relatives did not show increased risk. Therefore, genetic factors were found to contribute to risk, but family environment was not.

The family, twin, and adoption studies indicate that bipolar disorder aggregates in families and is heritable. However, since the concordance rates in MZ twins do not approach 100%, genetics alone is not a sufficient explanation for the occurrence of bipolar disorder. There must be non-genetic causes as well.

Recently, genetic research has focused on the identification of the means of transmission through studies of linkage and association. Linkage refers to the identification of a chromosomal region containing an "illness" gene, whereas association refers to the identification of particular characteristics more frequent in patients than controls. Initial positive linkage results were found for the X chromosome as well as chromosome 11, but these have not been replicated. More promising results have been found to implicate chromosomes 18 and 21 (Alda, 1997).

6.16.4.3 Life Events

6.16.4.3.1 Life events in unipolar disorder

Since the 1960s, a voluminous literature has indicated a relationship between stressful life events and increased risk for unipolar depression. Paykel (1994) reviewed 28 studies in which more negative life events were reported by depressed people prior to episode onset than were reported in a similar period by people who did not become depressed. Similar results have also been obtained using community samples (Brown, Ahmed, Gary, & Milburn, 1995; Brown, Adler, & Bifulco, 1988), and samples of depressed children (Goodyer, Herbert, Tamplin, Secher, & Pearson, 1997). The association between stressful life events and depression appears to be stronger for nonmelancholic depressions; evidence for the link between melancholic depression and precipitating life events remains less well documented (Brown et al., 1994).

Despite the research directed into this area, the strength of the causative link between stressful life events and unipolar depression remains difficult to gauge. Depression, be it melancholic or nonmelancholic, is a heterogeneous illness with many causative, perpetuating, and modifying factors. Most individuals experience stressful life events and do not develop depression. Rather, life stress interacts, or is additive with, other predisposing factors to induce depression.

Researchers have investigated what types of events may be especially "meaningful" to individual persons and as such may particularly dispose them to development of depression. Beck and colleague's Sociotropy-Autonomy Scale (SAS; Beck, Epstein, & Harrison, 1983) distinguishes sociotropic people, those for whom affiliation with others is especially important, from autonomous people, those for whom issues of achievement and failure are paramount. Hammen, Ellicott, Gitlin, and Jamison (1989) found that patients who experienced stress consistent with their SAS type reported significantly more depressive symptoms than those who did not, despite no overall difference in the amount of stress experienced.

There has also been some study of the possibility that different types of events may differentially dispose people to depressive versus anxiety responses. In a community sample of 400 adult women, Brown (1993) found that loss provoked the onset of depression, danger provoked anxiety, and a combination of the two types of stressors provoked comorbid anxiety and depressive disorders.

Other researchers have examined how the association of stressful life events, maladaptive coping responses, and depression may be interrelated. Bifulco and Brown (1996) found that, in a person's reaction to severe events, the negative cognitive coping responses of inferred denial, self-blame, and pessimism were associated with increased depression risk, whereas a positive cognitive coping response, downplaying, was not.

Depressed persons may also create more negative life events than persons not prone to depression. Cui and Vaillant (1997), in a prospective study, found that depressed men experienced a greater amount of self-induced (dependent) negative life events after their first episode. The authors concluded that depression can generate these dependent negative events, and that this in turn may contribute to the chronic nature of the disorder. Similarly, Hammen (1991) found that women with unipolar depression, but not bipolar disorder, experienced more stressful life events and more dependent events than women with chronic medical illness, or with no physical or psychological impairment. She theorized that these women tended to generate stressful conditions for themselves, particularly in the interpersonal domain, which further contributed to their ongoing cycle of depressive symptoms and stress.

Research into the interaction of genetic factors and life events has also indicated that depressed persons play a role in bringing about their own negative stressors. Using a large sample of female twins, Kendler and Karkowski-Shuman (1997) found that genetic liability to depression was associated with a greater risk for assault, serious marital problems, divorce or breakup, job loss, serious illness, or financial problems. The authors suggested that genetic liability for depression is associated with greater life stress because genetic factors increase the likelihood that these individuals will place themselves in high risk environments.

Finally, some research has indicated the importance of positive events in the recovery from depression. Brown et al. (1988) and Brown (1993) found that, in women with chronic depression, life events that promise some hope for a better future, termed "fresh start events," were associated with recovery or improvement, even if these events were threatening.

6.16.4.3.2 Life events in bipolar disorder

The role of psychosocial stressors is not as well understood in the onset and course of bipolar disorder as it is in unipolar disorder. This is largely because bipolar disorder is more heavily determined by biological factors, in particular genetics. Even though bipolar illness is considered largely biological in nature, the impact of life events and psychosocial stressors have been shown to influence recovery and relapse from affective episodes in bipolar patients (Johnson & Roberts, 1995).

Bipolar patients have been found to have a higher number of severe stressors in the six months prior to the onset of a manic episode, compared to nonpsychiatric controls (Kennedy, Thompson, Stancer, Roy, & Persad, 1983), but no more so than unipolar depressive or schizophrenic patients (Johnson & Roberts, 1995).

Negative life events also affect relapse in patients with bipolar disorder. Ellicott, Hammen, Gitlin, Brown, and Jamison (1990) found that patients who had the highest total life event scores had a risk of relapse 4.5 times that of patients who did not experience stress. Similarly, Hunt, Bruce-Jones, and Silverstone (1992) found the rate of severe negative life events was significantly higher in the three months before relapse than in periods of time that did not precede relapse. Rates were especially elevated in the month just before relapse, such that severe negative events were four times more likely in the month prior to relapse than during other months. Other researchers have found that patients with bipolar disorder are more susceptible to the effects of severe stressors, such as a hurricane, than persons without bipolar disorder (Aronson & Shukla, 1987; Hammen & Gitlin, 1997).

Negative life events may also delay time to recovery for patients who are experiencing a manic episode. Using a prospective design, Johnson and Miller (1997) found that those who experienced a major stressor during a manic episode took three times as long to achieve a full recovery than those who did not experience a major stressor.

A hypothesized mechanism by which stressful life events might precipitate relapse is through alteration of circadian rhythms. Models employing this hypothesis have posited that stressful life events disrupt normal social–environmental cues and physiological rhythms, including sleep and neuroendocrine functioning. Such disturbances in physiological processes may precipitate manic and depressive episodes in vulnerable individuals (Johnson & Miller, 1997).

6.16.4.4 Effects of Early Environment on Unipolar Disorder

The onset of depressive episodes is associated with environmental circumstances that can serve as proximal causes, as described in Section 6.16.4.3.1. The effect of such life events could be to expose a genetic vulnerability, but they may also reveal a vulnerability that is in large part created by events in childhood, long before the emergence of depressive symptoms. Early empirical efforts to isolate predisposing events in childhood focused on parental loss, especially the child's bereavement experience, as a risk factor for later depression. More recently, the childhood home environment of depressed adults has been studied, primarily through their recollection of their parents' attitudes and behaviors.

With the availability of dozens of studies that have examined the association of parental loss to later depression, it has become possible to separate the effects of different types of loss, such as parental death, separation, or extended absences (Parker, 1992). When examined carefully, parental death during childhood, long believed to predispose an individual to adult depression, has not consistently been found to be related to the disorder. Rather, parental separations, especially those that reflect or result in family discord, are the types of "loss" that are most clearly and consistently associated with later depression. This analysis of the effects of parental loss focuses on the nature of the parenting environment, rather than the experience of bereavement in childhood *per se* (Brier, Kelsoe, Kirwin, Beller, & Wolkowitz, 1988;

Harris, Brown, & Bifulco, 1986; Tennant, 1988). Researchers have thus turned their attention to the effects of parenting, with or without parental loss, as they may predispose a child to depression in adulthood.

The most frequently studied parenting styles in this domain concern the two dimensions of (i) parental care (ranging from caring to unaffectionate style), and (ii) parental protection (from appropriate encouragement of autonomy to overprotective style). Lack of care is hypothesized to predispose the child to lasting self-esteem problems. Overprotection is thought to deprive the child of education in self-reliance and problem-solving behaviors, which may result in a sense of helplessness and hopelessness when stressors are encountered in later adult life (Perris, 1988).

Several studies of parental style have used the Parental Bonding Instrument (PBI; Parker, Tupling, & Brown, 1979), a retrospective measure of parents' behavior during the respondent's childhood. High scores on two dimensions of the PBI, low care and overprotection, have been associated with higher depression levels in clinical (Hickie et al., 1990) and community (Parker, Hadzi-Pavlovic, Greenwald, & Weissman, 1995) samples. This combination of styles has been termed "affectionless control."

These findings appear to be specific to nonmelancholic depression. Research has revealed no association between low care or overprotection and adult melancholic depression (Parker & Hadzi-Pavlovic, 1992; Parker, Kiloh, & Hayward, 1987). The association of parental affectionless control and later adult nonmelancholic depression (but not melancholic depression) has recently been replicated, using a non-Western sample of depressives and controls (Sato, Sakado, Uehara, Nishioka, & Kasahara, 1997).

Research shows that the repercussions of parents' use of affectionless control are additive. That is, if both parents exhibit the affectionless control style, the risk for later depression is greater than if only one parent does so; the risk is decreased if one parent exhibits optimal (high care–low control) parenting style (Parker & Hadzi-Pavlovic; 1992).

The research findings cited thus far do not prove that a parenting style of affectionless control is a cause of depression. Some noncausal explanations, however, have been ruled out. Depressed persons' reports of parental low care and overprotection do not appear to be the consequence of (i) response bias in the form of a blaming personality style (Hickie et al., 1990), (ii) retrospective bias resulting from a depressed mood state (Gerlsma, Das, & Emmelkamp, 1993), (iii) a propensity to help-seeking behavior (Parker et al., 1995).

However, other noncausal relationships have not been ruled out. Genetic factors common to parent and child could both predispose the parent to a style of affectionless control, and the child to the development of depression. Alternatively, premorbid child characteristics may themselves elicit pathogenic parenting. In this scenario, the child's behavior is both an influence on parental behavior and a premorbid (temperamental) characteristic that is associated with later depression.

Recent findings from a study of adult female twins (Neale et al., 1994) are consistent with a model in which poor parental style causes depression. Fathers' influence on their daughters' depression status appeared to be due to their parental style, as well as to a genetic effect. Mothers' influence appeared to be due only to their parenting style, and not genetics. Further use of behavior genetic methods (adoption studies, twin studies) should help to clarify the role of parental style in the development of depression in later life.

6.16.5 COMORBIDITY

6.16.5.1 Comorbidity with Anxiety Disorders

There is substantial symptom overlap in depression and anxiety, including negative affect, restless sleep, decreased energy, irritability, worry, indecisiveness, and negative self-evaluation (Alloy, Kelly, Mineka, & Clements, 1990). Both anxious and depressed individuals attach unrealistically high probabilities to negative outcomes (Beck, 1967, 1976; Beck & Emery, 1985). The similarity in symptomatology is exemplified in the assessment instruments used to measure the constructs of depression and anxiety. For example, there is a 70% item overlap between the Hamilton Rating Scale for Depression (Hamilton, 1967) and the Hamilton Rating Scale for Anxiety (Hamilton, 1959; DiNardo & Barlow, 1990).

Prior to the publication of the *DSM-III-R* (APA, 1987), comorbid anxiety disorders were excluded in the presence of affective disorders. It was presumed that affective disorders held a higher position in the classification system. This hierarchical classification was modified in the *DSM III-R* and *DSM-IV* to allow for additional diagnoses of anxiety disorder (i.e., panic disorder, agoraphobia, obsessive-compulsive disorder, generalized anxiety disorder) in the presence of a major depression.

When anxiety–depression comorbidity is recognized, as it is in the *DSM-IV*, persons with a major depressive disorder are found to be more than 10 times as likely to be diagnosed with an anxiety disorder than are nondepressed persons (Boyd et al., 1984). High rates of depression are commonly found in the course of anxiety disorders, especially in individuals with panic disorder, agoraphobia, and obsessive-compulsive disorder (Akiskal, 1990). Although cases of anxiety without depression are relatively common, cases of depression in the absence of anxiety are quite rare (Hamilton, 1983). There is some evidence that anxiety tends to precede the onset of depression, and may be a response to the debilitating effects of anxiety. Once established, anxiety disorders are not uncommonly followed by a depressive disorder, whereas depressive disorders are rarely succeeded by an anxiety disorder. Angst, Vollrath, Merikangas, and Ernst (1990) reported that 49% of their cases with pure anxiety disorders went on to develop depression, whereas only 33% of the cases with pure depression later developed an anxiety disorder.

Merikangas (1990) reviewed family and genetic studies of anxiety and affective disorders, which provide some evidence for a common genetic pathway for these disorders. Although the results of this review were inconsistent with respect to familial overlap, nearly all the studies reviewed found a high degree of comorbidity of anxiety and depression in the probands and to a lesser extent, their relatives. Families in which probands exhibited both anxiety and depressive symptoms resembled depressed families more so than families of probands with anxiety disorders alone. Likewise, families of probands with anxiety or panic disorder without depression did not tend to have increased familial loading for depression. In addition to finding support for the notion of pure forms of anxiety and depression breeding true, there was also substantial evidence for a mixed form of anxiety–depression in which anxiety and depression in families appear to have a common underlying genetic contribution. More recently, in a study of 133 depressed and 82 controls probands, Merikangas, Risch, and Weissman (1994) assessed patterns of comorbidity and cotransmission of anxiety disorders, major depression, and alcoholism. Their findings indicated that anxiety, depression and alcoholism are cotransmissible in families. This relationship was especially strong for anxiety disorders and major depression. Interestingly, their cotransmission analyses indicated that the observed comorbidity could be explained entirely by transmitted (i.e., genetic) rather than environmental factors. This finding supports the hypothesis that these disorders are manifestations of a shared genetic factor.

6.16.5.2 Comorbidity with Substance Use Disorders

Another type of Axis I disorder commonly found among individuals with affective disorders involves alcohol and substance abuse and dependence. Among individuals with major depression the lifetime prevalence rates for alcohol use and substance use disorders are 17% and 18%, respectively (Regier et al., 1990). When these figures are used to calculate odds ratios (the increased risk of developing a substance use disorder associated with depression), individuals with major depression are 1.5 times more likely to have a comorbid alcohol use disorder and 1.8 more likely to develop a substance use disorder.

In the ECA study, bipolar disorder was found to have the highest comorbidity with drug or alcohol abuse of all the Axis I disorders (Regier et al., 1990). The lifetime prevalence of alcohol-use disorders in individuals with bipolar disorder was 46%, which represents a risk ratio of 5.3. The percentage of substance abusers among individuals with bipolar illness was 34%, equivalent to an odds ratio of 8.3. Among patients in treatment for bipolar illness, cocaine and alcohol appear to be the most common agents of abuse (Fogarty et al., 1994; Sonne, Brady, & Morton, 1994). Initially, substance abuse during a manic episode may simply be part of the pattern of excessive and risky behavior. However, repeated substance use may cause changes in the mood-regulating centers of the brain, which then leave the brain more vulnerable to recurrences of affective episodes (Post et al., 1986). This is similar to the kindling process that may result from affective episodes themselves. In each case, it may be that there is a permanent degradation of brain regulatory processes.

One hypothesis regarding the increased risk of alcohol and substance abuse among individuals with affective disorders is that their use serves to alter negative mood states (Kantzian, 1985). Freud (1884, cited in Goodwin & Jamison, 1990, p. 223), recognizing its mood elevating properties, believed that cocaine could be used as a potent antidepressant. However, manics' increased cocaine use appears to be related to their attempts to enhance or prolong euphoric mood states, rather than to ameliorate depressive symptoms (Weiss & Mirin, 1987).

Evidence for a common genetic pathway of alcohol use disorders and affective disorders is inconclusive. Studies examining this issue have compared the prevalence of illness in relatives of patients against that found in controls. The concept of depression spectrum disease (Winokur, Cadoret, Dorzab, & Baker, 1971) came from the finding that unipolar depressed patients with alcoholic relatives differ in important ways from those without such relatives. Specifically, female relatives of patients with early-onset depression were more likely to be depressed, whereas male relatives were more likely to be alcoholic. Depressions could be divided into pure depressive disease (only depressions in the family) and depression spectrum disease (depressions with family histories of male alcoholism). Although many family studies have not shown an increase in alcoholism in the relatives of depressed patients (Merikangas & Gelernter, 1990), several adoption studies have demonstrated an increase in alcoholism in the biological relatives of depressed adoptees (Cadoret et al., 1996; von Knorring et al., 1983; Wender et al., 1986). Cadoret et al. concluded that the findings of adoption studies indicate the presence of a genetic factor for which alcoholism is a marker, and that a gene–environment interaction is an important etiological factor in depressive spectrum disease. Whereas the relationship between unipolar depression and alcoholism is mixed, it is clear that alcoholism does not belong in the genetic spectrum of bipolar manic-depressive illness (Gershon, 1990).

6.16.6 SUICIDE

Suicide is the ninth leading cause of death in the USA, accounting for more than 31 000 deaths in 1995 (Anderson, Kochanek, & Murphy, 1997). It is estimated that psychiatric illness is implicated in suicide 90% of the time (Goldstein, Black, Nasrallah, & Winokur, 1991). Affective illness is a well-established risk factor for suicide, and as such is a psychiatric disorder associated with serious risk of mortality. Indeed, the estimated lifetime probability for suicide among psychiatric patients with affective disorder is 15% (Guze & Robins, 1970).

Several risk factors for suicide in psychiatric and community samples have been identified, including demographic variables such as male gender, divorced or widowed civil status, unemployment, and older age (see Hawton, 1992, for a review). Psychiatric history variables, other than affective disorder, have also been investigated. Alcoholism (Martin, Cloninger, Guze, & Clayton, 1985), previous suicide attempts (Borg & Stahl, 1982), past psychiatric hospitalizations (Pokorny, 1983), and premature termination or unfavorable outcome of therapy (Dahlsgaard, Beck, & Brown, 1998; Goldstein et al., 1991) are associated with increased suicide risk.

Most recently, research efforts have been focused on what presenting symptoms, or psychological variables, may predict suicide in patients suffering from affective disorders. Unlike demographic and psychiatric history variables, psychological variables are considered "modifiable risk factors" (Fawcett et al., 1990), in that they may change as a result of treatment. One such factor is hopelessness. Hopelessness in the depressed patient manifests itself as a belief that there are no solutions to serious life problems, and that the future holds no respite from intolerable life circumstances. In inpatients hospitalized with suicide ideation, hopelessness has been found to be a better predictor of suicide than depression (Beck, Steer, Kovacs, & Garrison, 1985); it has also been found to predict suicide for up to one year after its assessment (Fawcett et al., 1990). In outpatients, hopelessness has also been demonstrated as a significant predictor of eventual suicide (Beck, Brown, Berchick, Stewart, & Steer, 1990; Beck, Brown, Steer, Dahlsgaard, & Grisham, in press).

The insidious nature of hopelessness in depression is illustrated in studies by Young et al. (1996) and Dahlsgaard et al. (1998). In both studies, suicide was not predicted by levels of hopelessness assessed at the beginning or middle of treatment. In Young et al., suicide attempts were predicted by high, stable levels of hopelessness assessed when these patients' depressive episodes had remitted. Similarly, Dahlsgaard et al. found that suicide was most likely to occur in patients whose levels of hopelessness did not decrease during treatment.

Anxiety symptoms have been related to suicide in work by Fawcett et al. (1990). Severe psychic anxiety, including the presence of panic attacks, and anxiety symptoms such as insomnia and diminished concentration, were strongly related to completed suicide occurring within one year of their assessment.

Suicide ideation has also been proposed as an obvious, and in principle modifiable, risk factor for suicide. However, communication of suicide ideation at initiation of clinical contact has not been found to predict eventual suicide (Beck et al., 1985). More powerful predictions can be made from retrospective reports of suicide ideation at its most severe point (Beck et al., in press).

Biological markers of suicide risk have recently been discovered. Indications of deficits in the neurotransmitter serotonin have been observed in depressed suicide attempters (Lester, 1995). This has been found to be especially true in those with more serious attempts (Mann & Malone, 1997), and those who went on to complete suicide within 1 year (Nordström et al., 1994).

6.16.7 THEORIES AND TREATMENTS OF UNIPOLAR DISORDER

6.16.7.1 Biological Theories and Treatments of Unipolar Disorder

There is no one biological theory of unipolar depression. Instead, the biological characterization of the state of depression is quite complex and incomplete, and it involves many biological systems and levels of analysis. One can begin at the level of the neurotransmitter, which is where modern theories of the biology of depression have focused. Abnormalities in hormonal functioning, as well as structural abnormalities in the brain, have also been examined.

In its simplest form, the amine theory of depression, originally proposed by Schildkraut (1965) and Glassman (1969), is that depression is caused by decreases in brain levels of the neurotransmitter norepinephrine (NE) or serotonin (5-HT), both of which belong to a class of neurotransmitters called amines. Evidence for this theory came in part from observing neuronal effects of drugs that reduce depressive symptoms. The tricyclic antidepressants (TCAs) inhibit the reuptake of NE and 5-HT into the presynaptic terminal. The inhibition of reuptake is presumed to make more amines available for neurotransmission, which in turn is presumed to return the amine systems to normal levels of functioning. Normal amine functioning, in turn, translates into normal mood functioning (but see Richelson [1991] who argues that the amine effects explain the side effects, not the therapeutic actions of the drugs).

The amine story cannot be as simple as the version described above. The effects of TCAs on the inhibition of reuptake are nearly immediate, yet these drugs take more than a week to exert their therapeutic effect. A partial explanation of this delay involves a regulatory system called the α_2 autoreceptor. This receptor, which sits on the presynaptic membrane, regulates the release of NE into the synapse by detecting how much NE is in the synapse already, and inhibiting the further release of NE. After days or weeks of treatment, during which time the α_2 autoreceptor is fighting to maintain the pretreatment synaptic level of NE, it downregulates. This means that it reduces its activity, and thereby allows more NE to be released into the synapse.

An even more sophisticated analysis of the role of amines in depression has recently been articulated by Heninger, Delgado, and Charney (1996), based on findings from biological challenge tests. Heninger et al. conclude that the role of amines is to regulate other biological mechanisms, likely to be found within nerve cells, that have a more direct effect on mood and other symptoms of depression.

The brain structure most consistently implicated in mood disorders is the hypothalamus. The effect of hypothalamic activity on other biologic systems has thus been of great interest (Musselman & Nemeroff, 1996). Hypothalamic activity affects the pituitary gland, which in turn affects activity in the thyroid and adrenal glands. Abnormalities of thyroid activity have been found in depressed patients, and medication treatments that include the use of synthetic thyroid hormone have been found to be effective. The adrenal hormone cortisol, commonly considered a stress hormone, tends to be elevated in depressed people. Moreover, the cortisol regulation system, as assessed by the dexamethasone suppression test (DST), is impaired in many depressed patients.

Individual tests of thyroid and adrenal malfunction have thus far not been sensitive and specific enough to guide diagnosis and treatment. Not surprisingly, the combined results of several tests yield better results. For example, when Banki, Arato, Papp, Rihmer, and Kovacs (1986) used four neuroendocrine tests, they found that 11 of 21 (52%) depressed patients obtained abnormal results on at least three of them. Only 3 of 44 (7%) of nondepressed psychiatric patients, and 0 of 15 nonpsychiatric patients, achieved a similar result.

In addition to neurotransmitter and neuroendocrine abnormalities, abnormalities of brain structure have been identified (Soares & Mann, 1997). Although global brain atrophy has not been found, the basal ganglia, the cerebellum, and the frontal lobe appear to be reduced in size in unipolar depression. Each of these areas has connections to brain structures known to participate in the regulation of mood. For example, the cerebellum projects to norepinephrine cell groups in the limbic system. Therefore, cerebellar atrophy is suspected to play a role in the inability of the limbic system to regulate processes that are responsible for normal mood functioning.

The major biological treatment modalities for unipolar depression are medication and electroconvulsive therapy. Antidepressant medications fall into three classes: tricyclic antidepressants, selective serotonin reuptake inhibitors, and monoamine oxidase inhibitors.

Treatment of depression with antidepressants is effective in cases of moderate to severe depression. The utility of medicines for milder forms of depression, however, is in doubt. Elkin et al. (1989) found no advantage of the antidepressant medication imipramine over a placebo condition for patients who, at intake, scored below 20 on the Hamilton rating scale for depression (Hamilton, 1967). The advantage of imipramine over placebo was clear, however, among the more severely depressed patients (see also Paykel, Hollyman, Freeling, & Sedgwick, 1988; Stewart et al., 1983). Typical symptom clusters that predict a favorable response to antidepressant medications are: decreased appetite, insomnia, acute onset, a family history of depression, and a personal or family history of positive response to antidepressant medications or electroconvulsive therapy (APA, 1980).

The efficacy of TCAs is demonstrated most thoroughly by research on imipramine. The oldest and most widely prescribed TCA, its most common brand name in the USA is Tofranil. Imipramine has been compared to placebo in nearly 50 double-blind studies. The combined findings reveal a 65% improvement rate with imipramine, compared to 30% with placebo (Goodwin, 1992). Other commonly used TCAs are amitriptyline (Elavil) and doxepin (Sinequan).

As with all medicines, side effects can occur with TCAs. Common cardiovascular side effects include tachycardia (increased heart rate) and postural hypotension (a sudden drop in blood pressure when arising from a bed or a chair). Neurological side effects are fairly common, especially sedation. Due to the neurological and cardiovascular toxicity of TCAs, the use of these medicines in suicide attempts is a serious risk. For this reason, special caution is exercised when these drugs are used to treat suicidally depressed patients.

Administration of selective serotonin reuptake inhibitors (SSRIs) is indicated in the same cases of depression that indicate administration of TCAs—moderate to severe depression of a fairly typical character. These newer antidepressants are often preferred to TCAs because they exhibit comparable effectiveness but have reduced side-effects and a much reduced overdose potential relative to TCAs (see Greenberg, Bornstein, Zborowski, Fisher, & Greenberg's [1994] meta-analysis of fluoxetine [Prozac] outcome). Besides fluoxetine, other commonly prescribed SSRIs are paroxetine (Paxil) and sertraline (Zoloft). Common side effects of the SSRIs tend to be gastrointestinal or sexual, including nausea, diarrhea, and sexual dysfunction. Decreased appetite, nervousness, and tremor are also reported (Guze & Gitlin, 1994). Because the cardiac and neurological side effects are less than those of TCAs, SSRIs are associated with a much lower risk for use in lethal overdose.

Monoamine oxidase inhibitors (MAOIs) are generally indicated in cases of atypical depression that would not respond adequately to TCAs or SSRIs (Quitkin et al., 1993). The category atypical depression includes nonmelancholic depression, or depression with anxiety, rejection sensitivity, chronic pain, or the reversed vegetative symptoms of appetite increase and hypersomnia (Lam & Stewart, 1996). The medicines phenelzine (Nardil) and tranylcypromine (Parnate) belong to the class of MAOIs.

Whereas the TCAs and SSRIs are presumed to alter neurotransmission functioning by inhibiting reuptake of amines into the presynaptic cleft, MAOIs act through the inhibition of monoamine oxidase (MAO). MAO is an enzyme that breaks down norepinephrine, either in the synapse or in the presynaptic terminal (McNeal & Cimbolic, 1986).

Frequently reported side effects of MAOIs include headaches, dry mouth, insomnia, constipation, sedation, blurred vision, and nausea. Of particular interest is the potential for unpleasant, or even fatal, interactions of MAOIs with foods containing high levels of tyramine. While taking MAOIs, one must avoid aged cheeses, red wines, soy sauce, smoked fish, and other foods containing tyramine (Davidson, 1992).

Electroconvulsive therapy (ECT) is generally considered a last resort treatment, to be used with patients whose depression severity requires hospitalization, or those who are not adequately responsive to antidepressant medications (Fink, 1992). There are cases, however, in which ECT is considered a primary treatment, such as when a rapid treatment response is needed, when risks of medications are greater than those of ECT, when a poor history of drug response and/or a positive history of response to ECT exists, or when the patient prefers ECT to other treatments. ECT is especially effective when depression is accompanied by psychosis or marked psychomotor retardation and depressive stupor (Enns & Reiss, 1992; Fink, 1992).

ECT has been shown to be more effective than sham ECT in double-blind controlled studies in the treatment of major depression (Gregory, Shawcross & Gill, 1985). Further, ECT has been shown to be more effective than moderate doses of TCAs (Ghangadhar, Kapur, & Kalyanasundaram, 1982).

Although the mechanisms through which ECT achieves its antidepressant effects are poorly understood, it is known that the induction of a *grand mal* seizure is essential for the success of ECT. One possibility is that the release of norepinephrine and dopamine during the seizure leads to overall improvement in the functioning of amine systems (Sackeim, 1989).

Patients with major depression generally receive seven to nine treatments, three times per week, with improvement generally evident after four or five treatments. The most common side effects associated with ECT as it is currently implemented are cognitive impairment and memory loss. Although memory loss is generally limited to the periods around the time of the treatments, some patients report loss of memory of events that occurred before ECT, or even before the depressive episode (Fink, 1992).

6.16.7.2 Cognitive Theories and Treatments of Unipolar Disorder

The cognitive theory has been the most influential psychological theory of depression since the 1970s. Its heuristic value as a way of describing the experience and behavior of the depressed person has been widely accepted. Its value as an etiological theory and as a basis for treatment, especially in severe forms of depression, has been more controversial.

Beck's (1967) early writings about depression came against the backdrop of the influence of psychoanalytic understandings of depressive phenomena. He argued that cognitive phenomena that are available to introspection are at the core of, and can explain the presence of, the other features of depression. Depressive mood is said to be the natural consequence of negative beliefs about the self, the future, and the world (the negative cognitive triad). Likewise, behavioral disturbances, such as response initiation deficits, are seen as resulting from a belief in the futility of action. For example, whereas in a psychoanalytic formulation of depression the failure of a depressed person to keep an appointment for a job interview might be interpreted as an instance of unconsciously motivated self-punishment, the cognitive model would focus on the negative expectations of the depressed person (e.g., "I'll make a fool of myself"; "I'll never get that job anyway"). Findings from literally hundreds of studies (Haaga, Dyck, & Ernst, 1991) have supported this characterization of the thinking of depressed people.

What makes a person vulnerable to this kind of thinking? Is depressive thinking, like sleep disturbance, merely a symptom of depression that arises during the episode, or are there premorbid cognitive phenomena that act as vulnerabilities? Beck has argued that depressed people possess "depressive schemas" even before the first onset of a depressive episode. However, because these schemas are latent, they are difficult to detect. Miranda and Persons (1988) have proposed that latent schemas can be detected, in principle, by assessments conducted when the vulnerable person is in a sad mood (Hedlund & Rude, 1995).

A research literature relevant to the question of cognitive vulnerability concerns the reformulated learned helplessness, or hopelessness, model of depression (Abramson, Metalsky, & Alloy, 1989). According to this model, vulnerability to depression is in the form of characteristic ways of explaining events, especially bad ones. This pattern is referred to as a depressogenic inferential style. The person with this style has a tendency to attribute bad events to causes that are internal (due to, or inherent in, the person), stable (likely to persist over time), and global (applicable to many domains of the person's life). Given this style, the occurrence of a bad event is especially likely to lead to specific depressogenic inferences, which will then lead to negative expectations, or a state of hopelessness. The state of hopelessness then generates the other symptoms of depression.

Research findings have yielded equivocal support for this model (Barnett & Gotlib, 1988). Abramson, Alloy, and Metalsky (1988) argue, however, that many investigators have used research designs that are not appropriate to test the set of hypotheses embedded in the hopelessness model. A large study designed specifically to test the hopelessness model is near completion; its findings strongly support the hypothesis that cognitive vulnerability interacts with stressful life events to produce the beliefs, and then the symptoms, associated with depression (Abramson, Alloy, Hogan, & Whitehouse, 1997; Alloy, Abramson, Murray, Whitehouse, & Hogan, 1997).

A critical aspect of any psychological model of depression is its ability to delineate distal causes. If there are persons who possess a thinking style that makes them vulnerable to depression in the face of negative life events, it is likely that both genetic (Schulman, Keefe, & Seligman, 1993) and environmental factors play a role in the development of that style. The recent findings reported by Garber and Flynn (in press) suggest that a relative absence of maternal acceptance and the presence of maternal psychological control contribute to the development of thinking styles characteristic of persons at risk for depression. These findings accord with the observation that depressed adults report having experienced a parental style of affectionless control (Parker, 1992). Garber and Flynn also found that whereas correlations between children's and parent's thinking styles were low, mothers' explanations of their children's behavior were related to their children's own explanations regarding their behavior. Hence, only on explanations of child-focused events, and not general thinking style, were mothers and children similar.

Beck's cognitive therapy for depression (Beck, Rush, Shaw, & Emery, 1979; DeRubeis & Beck, 1988) has for the last 20 years epitomized modern, brief, semistructured forms of psychosocial interventions for serious mental disorders. Two factors have been especially important in the popularity of this form of therapy for depression. First, beginning in 1977 (Rush, Beck, Kovacs, & Hollon, 1977), there has been a series of impressive demonstrations of the efficacy of cognitive therapy. Second, Beck et al.'s (1979) description of cognitive therapy, as detailed in their classic therapy manual, has been admired for its clarity, detail, and thoroughness. Professionals who find descriptions of psychoanalytic methods too unstructured, and behavior therapy too restrictive, find a middle ground in cognitive therapy. Similarly, it has captured a segment of the educated public, who find that the ideas embedded in cognitive therapy (Burns, 1980) are both practical and consistent with common sense.

The beginning assumption in cognitive therapy for depression is that depressed patients frequently engage in ill-considered negative thinking that, when held up to scrutiny, will be found in error. Although there has been an interest by some writers, beginning with Freud (1917/1957; Alloy & Abramson, 1982, 1988), in the idea that depressed people see the world more clearly than nondepressed people, there is no good evidence for this view (Ackermann & DeRubeis, 1991). Moreover, this depressive realism hypothesis runs counter to common sense; the most interesting version of this hypothesis implies that the most severely depressed person will also be the wisest, clearest thinker. This proposition is, *prima facie*, incorrect if not foolish.

The therapist's first task in cognitive therapy, then, is to teach the patient to attend to their thoughts, some of which will be distorted. These thoughts may be quite prominent in the patient's attentional focus, even before the beginning of therapy, in which case the patient merely needs to learn to remember them or, better yet, write them down for further consideration. It may take extensive instruction and practice before the patient learns to capture the stream of thoughts that accompanies almost any experience. Of course, the greatest efforts are directed at observing thoughts that occur before, or during, an unpleasant emotional state, such as sadness or despair. The term "automatic thoughts" has been used to refer to the spontaneous nature of many of these thoughts. Their automatic, effortless, tacit, and habitual nature can make them especially difficult to notice.

The kinds of negative thoughts most frequently reported by depressed patients involve beliefs about the self (e.g., "I'm worthless"), the future ("I'll never get another job"), or the world ("People are uncaring"), that is, Beck's (1967) negative cognitive triad. Hollon and Kriss (1984) classify automatic thoughts into (i) attributions, which are explanations about past events (e.g., "The breakup with my girlfriend was all my fault"); (ii) ascriptions, which are descriptions of present states (e.g., "I'm unlovable"); and (iii) expectations, which are predictions about the future (e.g., "I'll never marry"). However one classifies these thoughts, the assumption is that they are observable, either as (complete or partial) sentences, or as visual images (e.g., an image of oneself, old and alone, with no loved ones present). It is further assumed that many of the thoughts are incorrect or invalid, or that the implications depressed patients derive from the thoughts are exaggerated toward the negative (e.g., "Since my relationship is over, I will never find another good relationship").

For many patients, once the thoughts are noticed, they can be seen as exaggerations or distortions. Therapy is facilitated further when patients write the thoughts on paper. The concreteness of thoughts written down lends them to serious, dispassionate reconsideration.

The next element of therapy, then, entails teaching the patient the most effective means of reconsidering their thoughts. Four classes of questions address most thoughts reported in therapy. The first question is, "What is the evidence that the thought is true, or not true?" The first half of the question is aimed at getting the patient to explicate the basis for a belief; the second half will challenge the belief, if there is relevant evidence to counter it. The second question is, "Are there alternative explanations that have not been considered?" This question is especially relevant when patients assign self-blame inappropriately or excessively. The third question—"What are the implications if the belief is true?"—is directed at the tendency for depressed patients to imagine exaggerated consequences of real failures or shortcomings. The fourth question—"What can I do?"—follows from the others. Once a problem has been identified, relatively free of distortion and exaggeration, a plan of action can be developed rationally.

Cognitive therapy has also been called cognitive behavior therapy, in part because the fourth question focuses on action. Moreover, especially early in treatment, behavioral techniques are employed to counter the failure of depressed people to initiate action that could lead to pleasure or a sense of accomplishment. Cognitive therapists help patients break tasks into their smaller components, and to plan to engage in activities they have been avoiding. At each point, the cognitive therapist is interested both in increasing the patient's engagement in the world, and in discovering the distorted beliefs that have prevented them from doing so during the depression.

Cognitive therapy is a skills-based treatment (Barber & DeRubeis, 1989). The hope is that patients will not only benefit from the therapists' interventions, but that they will learn how to apply the interventions to themselves. But cognitive therapy, especially as recent writers have described it (Persons, 1989), is also a kind of insight therapy. Therapists help patients to discover idiosyncratic patterns of belief, or schemas, that they apply across a wide range of situations. Therapy can then focus on the developmental origin of the schemas. Many modern cognitive therapists believe that therapy is unsuccessful if it does not include the identification of schemas and their origins. However, all of the outcome research has been conducted with therapists who have not placed great emphasis on the schema aspect of cognitive therapy. It remains to be seen whether it is the acquisition of skills, or the understanding of themes and origins, that is most critical to the success of cognitive therapy (Barber & DeRubeis, 1989).

In 1977, Rush, Beck, Kovacs, and Hollon published the first findings indicating that a psychosocial treatment could intervene in a depressive syndrome as quickly and effectively as a pharmacological treatment. In fact, due in part to a design artifact, cognitive therapy was said to be significantly more effective than imipramine pharmacotherapy in that study. Findings from subsequent studies (Hollon et al., 1992; Murphy, Simons, Wetzel, & Lustman, 1984) converged on the conclusion that cognitive therapy is as effective and as fast-acting as antidepressant medications as an acute treatment of depressed outpatients. Moreover, follow-up results from these studies, especially the Evans et al. (1992) follow-up of the Hollon et al. study, suggested that short-term cognitive therapy prevents relapse relative to equally short-term pharmacotherapy (Hollon, Shelton, & Loosen, 1991).

These conclusions were widely accepted until the publication of findings from the large, multicenter Treatment of Depression Collaborative Research Program (TDCRP; Elkin et al., 1989). Whereas none of the previously mentioned studies included a control group in their design, the TDCRP included a pill-placebo condition, as well as cognitive therapy, imipramine pharmacotherapy, and interpersonal therapy conditions. In the TDCRP, cognitive therapy did not outperform placebo significantly, and some analyses of the outcome data indicated that imipramine was more effective than cognitive therapy for the more severely depressed patients (Elkin, Gibbons, Shea, & Sotsky, 1995). This pattern of findings from the TDCRP led the APA (1993) to publish treatment guidelines that questioned the effectiveness of cognitive therapy for depression, especially in its more severe forms. Recently, DeRubeis, Gelfand, Tang, and Simons (1998) have reanalyzed data from only the more severely depressed patients from the Rush et al. (1977), Murphy et al (1984), Hollon et al. (1992), and TDCRP studies. Considering the patients in all four studies combined, cognitive therapy was at least as effective as medications during the acute treatment phase. Thus, treatment guidelines that focus only on the failure of cognitive therapy in the TDCRP appear to underestimate the short-term benefits of cognitive therapy for severely depressed outpatients. Further research on cognitive therapy and pharmacotherapy for severely depressed outpatients is currently being conducted. This study will also examine the putative relapse prevention benefits of cognitive therapy.

The specificity of cognitive therapy for depression, once inferred primarily from its equivalence to pharmacotherapy (Dobson, 1989), is now being questioned. Not only have there not been many comparisons of cognitive therapy to other psychosocial interventions, there has also been virtually no research comparing cognitive therapy to control conditions. In the TDCRP, cognitive therapy did not surpass the interpersonal therapy condition or the placebo condition. Indeed, there were some indications of the superiority of interpersonal therapy in that study, especially in the more severe sample. A recent study by Jacobson et al. (1996) suggested that behavior therapy is as effective as cognitive therapy for depression. Jacobson is following up this finding in a larger design that will include a pharmacotherapy group, as well as a placebo control. Indications of the potency of cognitive therapy gleaned from the studies summarized in DeRubeis et al. (1998) cannot be ignored, but the set of investigations currently underway will refine the answers to questions about the short- and long-term benefits of cognitive therapy for depression.

6.16.7.3 Behavioral Theories and Treatments of Unipolar Disorder

Lewinsohn (1974) has written most extensively about the role of behavior theory and behavior therapy in depression. In the behavioral view, depression is seen as the result of a low rate of positive reinforcement. The depressed person is unable to obtain gratification, either because there are very few reinforcing stimuli in their environment, or because of a deficit in skills, especially social skills. Depressed mood and behavior become part of a vicious cycle, in which depressive behavior, because others find it unpleasant, is especially unlikely to lead to positive reinforcement from others. According to this view, there are two promising points of entry in therapy for depression: acquisition of skills, especially social skills; and enrichment of the environment, by identifying, planning, and engaging in potentially reinforcing activities.

In two studies behavior therapy has outperformed control conditions. Shaw (1977) found that patients in his behavior therapy group improved more than those in a wait-list condition. (However, they improved less than those in his cognitive therapy group.) McLean and Hakstian (1979) conducted a large study in which they compared behavior therapy to psychotherapy, relaxation therapy, and amitriptyline pharmacotherapy. Significantly greater symptom change was observed in their behavior therapy condition than in each of the other three conditions.

In a recent study of 150 outpatients by Jacobson et al. (1996), behavior therapy produced as much change in depressive symptoms as either of two cognitive therapy conditions. This result was not due to poor outcome in the cognitive therapy conditions—recovery rates and mean end-of-treatment scores on standard measures were impressive in all three groups. Jacobson and colleagues are following up these findings with an even larger scale study that will pit behavior therapy and cognitive therapy against each other, as well as against medication therapy and a placebo control condition.

Nezu (1986) has described a behavioral program he calls problem-solving therapy, which assumes that depressed persons have lost (or never possessed) the skills necessary to solve life problems. Problem solving therapy has performed well in two controlled comparisons with depressed outpatients (Nezu 1986; Nezu & Perri, 1989). Problem solving approaches that are directed at the suicidal behavior of depressed people also appear to be promising.

Linehan (1993) has developed a cognitive behavioral approach to the treatment of chronically suicidal patients with borderline personality disorder. Termed dialectical behavior therapy (DBT), the goals of this treatment are to remediate deficits in interpersonal, emotion regulation, self-regulation, and distress tolerance skills, and to encourage the use of these skills, especially during times of suicide ideation. In a randomized comparison with a treatment as usual condition, DBT patients exhibited better overall adjustment, as well as anger control, at treatment termination (Linehan, Tutek, Heard, & Armstrong, 1994). Because the chronically suicidal borderline patient is considered especially difficult to treat, these preliminary indications of the effectiveness of DBT have been greeted with enthusiasm by practitioners and treatment researchers.

6.16.7.4 Psychodynamic Theories and Treatments of Unipolar Disorder

The earliest modern psychological theory of depression was described by Freud (1917/1957) in his classic paper, *Mourning and melancholia*. Central to Freud's theory was the proposition that loss precedes all episodes of melancholia, as it does in all instances of mourning. Freud delineated the similarities between mourning and melancholia, such as sad mood and decreased interest in people and activities, all of which could be accounted for by loss.

Freud then focused on the unique, defining features of melancholia, most importantly self-reproach, and suicidal thoughts and actions. He posited that desires to harm or punish oneself are best understood as deriving from a wish to harm the lost object, or some aspect of it. So, for example, the depressed person who fails to show up for a job interview could be seen as manifestly punishing or harming him- or herself, but the unconscious motive for this may be a wish to punish his or her deceased father. Necessary for the development of this wish to punish another object is a history of ambivalent love for that object. Under conditions of ambivalent love, when the object is lost and is incorporated into the self (ego), both the loved and hated elements of the object become part of the ego. From that point on, when a wish to retaliate against or harm the lost object occurs unconsciously, it is manifest as a wish to harm the self, through the defense of retroflection, whereby anger towards another is transformed into anger turned inward. Many mental health professionals believe that retroflected anger is an important basis for depressive symptoms, especially those that are self-defeating. Belief in the phenomenon of retroflected anger has formed the basis for the popularity of efforts to help depressed people release their anger. Nonetheless, there have been no systematic investigations of the effectiveness of Freudian psychoanalysis for depression, or of any treatment based on the anger-turned-inward hypothesis of depression.

Whereas the psychoanalytic theory of depression focuses on a pathological motivational system, and cognitive theory focuses on pathology of belief, interpersonal–psychodynamic theory of depression focuses on the pathological relation of the person to their interpersonal environment. The interpersonal theory of depression is a specific application of a general interpersonal theory of psychopathology, whose best known advocates are Meyer (1957) and Sullivan (1953). In the interpersonal theory of depression (Klerman, Weissman Rounsaville, & Chevron, 1984), four types of interpersonal pathology are elaborated. A given depressed person is expected to exhibit one or more of these. Abnormal grief refers to either a prolonged grief reaction, or a distorted grief reaction in which normal grieving processes do not occur. Interpersonal role disputes involve relationships that are one-sided or nonreciprocal. Abnormal role transitions refer to a person's inability to cope with life changes. Finally, interpersonal deficits are seen in people who have had a poverty of social relations throughout their lives.

The interpersonal theory of depression is associated specifically with a brief, structured psychosocial intervention for depression, termed interpersonal psychotherapy (IPT; Klerman et al., 1984). The benefits of IPT in depressed outpatients were first examined by DiMascio et al. (1979). IPT achieved symptom reduction equivalent to that observed in a medication condition, although the medications achieved their effects more rapidly. In comparison to a minimal contact control condition, IPT effects were superior.

Interpersonal therapy also performed well in the TDCRP (Elkin et al., 1989). At post-treatment, the depressive symptoms of IPT patients reached levels almost as low as those achieved in the medication condition, and slightly lower than those of patients treated with cognitive therapy. (Neither difference was significant.) When the authors examined data from the patients who were more severely depressed prior to treatment, there were some indications that IPT was superior to placebo.

Another psychodynamically based intervention, psychodynamic interpersonal psychotherapy (PI; Shapiro et al., 1994), has been examined as a treatment for depression. The main difference between PI and IPT appears to be that PI focuses more on the relationship between the patient and the therapist, using it as a vehicle for understanding the patient's interpersonal relationships more generally. In psychodynamic terms, PI attends to the transference relationship between patient and therapist. Shapiro et al. found that on some measures, PI performed as well as a version of cognitive behavioral therapy in a large sample of depressed outpatients. However, there were also some indications that PI was not as effective as cognitive behavior therapy.

Thus, although there has been little effort to test Freud's psychoanalytic treatment for depression, active research programs exist that aim to evaluate more structured versions of therapies that derive from psychoanalytic thought. This is part of a modern trend for psychodynamic thinking to be instantiated in short-term, focused interventions for specific disorders (Barber & Crits-Christoph, 1995).

6.16.8 THEORIES AND TREATMENTS OF BIPOLAR DISORDER

6.16.8.1 Biological Theories and Treatments of Bipolar Disorder

Neurochemical theories of mania invoke the same neurotransmitter systems as are implicated in unipolar depression. In Schildkraut's (1965) classic formulation, whereas depressive disorders were associated with a functional deficit of catecholamines (particularly norepinephrine), manias were said to involve a functional excess of catecholamines. The major metabolite of the catecholamine norepinephrine (NE), namely 3-methoxy-4-hydroxyphenylglycol (MHPG), has been shown to be elevated in bipolar patients when they were manic, compared with levels when depressed (Halaris, 1978). Similarly, bipolar patients, when manic, demonstrate significantly higher plasma NE and epinephrine levels than when they are depressed or euthymic (Maj, Ariano, Arena, & Kemali, 1984). Swann et al. (1987) reported that MHPG and NE levels in cerebral spinal fluid were significantly higher in manic patients than in either depressed or control subjects.

The permissive hypothesis of serotonin (Prange, Wilson, Lynn, Alltop, & Stikeleather, 1974) posits that a deficit in serotonergic transmission permits the expression of manic depressive illness, although a deficit is not sufficient to cause it. According to this theory, both the manic and depressive phases of bipolar illness are characterized by low serotonin (5-HT) function, but differ in terms of NE activity (high in mania, low in depression). Serotonin systems inhibit a variety of functions served by other neurotransmitters. Defective (low) serotonergic function, and the corresponding lack of inhibition of other neurotransmitter systems, especially NE and dopamine (DA), permits wide variations in affective symptomatology from depression to mania.

Goodwin and Sack (1974) analyzed the effects of drugs on the DA or NE system in relation to the relative efficacy of the drugs against different symptoms of mania. Their analysis led them to suggest that DA abnormalities are primarily involved in the hyperactivity and psychosis associated with the more severe stages of mania, whereas excesses in NE underlie the euphoria and grandiosity more characteristic of less severe forms of mania, or hypomania.

Janowsky, El-Yousef, Davis, and Sekerke (1972) postulated that an increased ratio of cholinergic to adrenergic activity underlies depression, and that the reverse is true in mania. In this view, mania results when increases in NE (an adrenergic transmitter) effect an imbalance relative to cholinergic (i.e., acetylcholine) activity. This hypothesis derives from the fact that antidepressant medications have substantial anticholinergic properties. Moreover, drugs that stimulate acetylcholine decrease manic symptoms in manic patients, and they increase depressive symptoms in depressed patients. These same drugs also induce depressions in nondepressed subjects.

Clinical and pharmacological data suggest that γ-aminobutyric acid (GABA) metabolism is altered in bipolar disorder. GABA has inhibitory input into other neurotransmitter systems such as NE and DA, and regulates many central nervous system functions, including seizure threshold. The role of GABA in convulsive disorders has been extensively studied, and antiepileptic drugs appear to act directly or indirectly on GABA. The antiepileptic agents valproic acid and carbamazepine were serendipitously noted to have a mood-stabilizing effect, decreasing the intensity and frequency of both manic and depressive phases of bipolar disorder. In addition to valproic acid, other antimanic agents, such as lithium and carbamazepine, appear to stabilize mood by increasing GABA-ergic transmission, leading to the hypothesis that GABA deficiency plays a role in mania (Bernasconi, 1982).

The behavior of the manic person, especially when agitated or violent, can be so extreme as to warrant immediate, aggressive therapeutic action. Medical management is almost always the first line treatment for a manic episode.

Lithium is the oldest of the modern antimanic agents. Lithium's antimanic properties were first discovered by John Cade in 1949, but it was not used in the USA until the 1960s. Since then, it has remained the medication of choice for mania. Plasma lithium levels must be monitored to maintain a therapeutic level, and to avoid toxic effects. The plasma level of lithium required to produce clinical response varies from patient to patient, and can vary within the same patient; patients in an active manic episode typically require higher dosages than they do to remain in a normal mood. Lithium is very effective in the treatment of acute mania; Goodwin and Zis (1979) reported a 78% overall response rate in a review of four double-blind, placebo-controlled studies. In addition to acute treatment, lithium is also effective in reducing future manic and depressive episodes in bipolar patients when used prophylactically (Prien, Caffey, & Klett 1974; see Goodwin & Jamison, 1990, for a review).

The anticonvulsants carbamazepine and valproate are also commonly used. They are used alone or in conjunction with lithium, and are commonly used in the treatment of lithium nonresponders. In a recent meta-analysis, Emilien, Maloteaux, Seghers, and Charles (1996) found the therapeutic efficacies of carbamazepine and valproate to be comparable to lithium in the treatment of acute mania. In Strömgren and Boller's (1985) review of 15 studies, 55% of patients were reported to have had a marked or moderate response to carbamazepine. Carbamazepine and valproate have both been shown to have prophylactic effects as well (Coxhead, Silverstone, & Cookson, 1992; McElroy, Keck, Pope, & Hudson, 1992).

6.16.8.2 Psychosocial Theories and Treatments of Bipolar Disorder

Psychosocial theories and treatments of bipolar disorder follow from an understanding that, although the disorder has predominantly genetic causes, its course is responsive to environmental stressors (Johnson & Miller, 1997). As adjuncts to medication therapy, psychosocial treatments aim to enhance medication compliance, and to increase resilience to stress. Miklowitz and Goldstein (1990) have developed family-focused treatment (FFT) for bipolar disorder. The goal of FFT is to reduce family conflict, which is believed to precipitate relapse. In the initial phase of FFT, patients and their families are educated about the symptoms of the disorder, the importance of medication compliance, and the strategies to employ if the patient begins to relapse. In the later stages of FFT, the psychoeducational focus is on improving family interaction—all family members learn communication and problem-solving skills (Miklowitz, Frank, & George, 1996).

A similar psychoeducational approach is found in the treatment known as interpersonal and social rhythm therapy (IPSRT; Frank et al, 1997). IPSRT methods were developed in recognition that irregular sleep and circadian patterns can be detrimental to the bipolar patient. Patients are shown that interpersonal stressors and social role transitions may upset daily routines, which in turn may disrupt circadian regularity and lead to relapse. During the course of therapy, patients are taught how to negotiate interpersonal dilemmas and role transitions, and they are coached in how to regularize and maintain stable daily routines, even when they encounter stressors in their environments.

Both FFT and IPSRT therapies are currently under investigation in randomized clinical studies. Preliminary results show that both treatments produce high patient retention rates through the first year of treatment (Miklowitz et al., 1996). In addition, IPSRT patients have demonstrated increasing stability of daily routines over the course of treatment (Frank et al., 1997).

Newman and Beck (1992) have described a cognitive model in which mania is characterized by a positive cognitive triad: the self is seen as highly valued and powerful, experience is viewed as overly positive, and the future is replete with opportunity. The distortions associated with this triad are the focus of cognitive theory and treatment.

Cochran (1984) found that the addition of a six-week cognitive therapy component reduced medication noncompliance, as well as the frequency of hospitalizations, during a six-month follow-up. More recently, Basco and Rush (1996) and Newman and Beck (1992) have given extensive descriptions of adjunctive cognitive-behavioral programs for bipolar disorder. The primary goals of these programs are to educate the patient, to increase adherence to medication regimens, and to promote the use of cognitive-behavioral techniques when confronted with affective symptoms. Education about bipolar illness includes instruction in the self-monitoring of prodromal symptoms. Awareness of subtle changes in symptoms or behaviors can then serve as a warning system for relapse. This warning system can cue the patient to have their medications monitored or increased. Efforts to facilitate adherence to medication regimens include addressing patient concerns and beliefs about medication. Behavioral techniques, such as pairing medication intake with another daily activity, are used to ensure that medication is taken regularly.

Cognitive therapy also focuses on the cognitive distortions of manic patients. For example, feelings of grandiosity are perpetuated by magnification of the positive and minimization of, or obliviousness to, negative feedback. Paranoid thinking in mania is reinforced by selective attention to evidence that confirms paranoid beliefs, along with dismissal of disconfirming evidence. These tendencies, as well as the patient's desire to maintain a manic or hypomanic state, are addressed with standard cognitive therapy methods.

In cognitive therapy, behavioral interventions are used to limit self-stimulating behaviors. Activities that have a high potential for dangerous consequences or which might serve to exacerbate the episode are identified early on, and the therapist helps to plan strategies for avoiding or limiting these activities. These include, as in IPSRT, maintaining a regular sleep schedule, as well as limiting spending, alcohol and drug use, and other risky behavior. Problem-solving skills are employed to address stressful life events that might precipitate relapse, and to address difficulties arising in the aftermath of an affective episode, such as the financial difficulties that result from excessive gambling or the loss of employment. Thus far, there have been no controlled clinical studies of cognitive therapy of bipolar disorder.

6.16.9 SUMMARY AND FUTURE DIRECTIONS

As we have seen, the affective disorders comprise a multifaceted, heterogeneous group. Heterogeneity is seen in the variety of causal influences, and in the perspective that is achieved by examining mood disorders from diverse vantage points. Indicative of this diversity is the extraordinarily broad array of effective treatments, from discussions of erroneous thinking in cognitive therapy to the induction of seizures by the electrical stimulation of the brain.

The greatest progress since the 1950s has occurred in diagnostic practices, phenomenological and biological characterizations, and in the development of effective treatments. The next half-century should produce further advances in these areas, but we will also witness the emergence of sophisticated and detailed causal theories that draw from the successes of the last half-century, especially once clarification is obtained about the subtypes of affective disorder. Genetic research, in particular, will inform us about the mechanisms involved in the development of brain processes in a person who is vulnerable to affective disturbance. Studies of the early social factors that lead to vulnerability in adulthood will also be critical in this period, as will research that yields more detailed understandings of the psychological states that predispose a person to mood disorder.

Attempts to understand affective disorders will succeed only if knowledge is integrated from several disparate areas of research. Explorations of the mechanisms and influences of genetics, research on parenting styles, investigations of cognitive styles, and elucidation of the roles played by the interpersonal environment and by life's difficulties will come together to inform a synthetic view of affective pathology and its treatment.

6.17.1 INTRODUCTION

Since the mid 1960s, many researchers have invested considerable effort in defining and characterizing obsessive-compulsive disorder (OCD) and its myriad symptoms, and, perhaps most importantly, in developing effective treatments. The results of these efforts by researchers, clinicians, patients, families, and their advocates, are that OCD is now a well-recognized condition, with effective and available pharmacological and behavioral treatments. In the late 1990s, newer forms of medications and of cognitive and behavioral interventions are under study. Consequently, it is likely that our knowledge of OCD and how to treat it effectively will continue to expand for some time. Below we present established and recent findings in the study of OCD.

6.17.2 SYMPTOMS AND CHARACTERISTICS OF OCD

6.17.2.1 Symptoms and Diagnosis of OCD

According to the *Diagnostic and statistical manual of mental disorders* (4th ed., *DSM-IV*) (American Psychiatric Association [APA], 1994), obsessions are recurring persistent thoughts, images, or impulses that are experienced at least at some point as intrusive, unreasonable, and distressing. The individual attempts to ignore or suppress these ideas or to "neutralize" them using some ritualistic thought or action. Compulsions are repeated behaviors or mental acts, rigidly or excessively applied to relieve anxiety provoked by the obsessions. Often, these rituals are designed to restore safety or to prevent a dreaded event (Rachman, 1976a), an intention that is often deliberately hidden from casual observers and even close family members. These symptoms interfere with the person's normal activities and consume at least an hour a day. As for many anxiety and affective disorders, in the general population, the symptoms of OCD are relatively common, but usually fail to meet the severity and interference criteria that characterize the disorder. It is interesting to note that the content of clinical obsessive intrusions differs very little from ordinary intrusive thoughts exhibited by most people, but the former provoke considerably more anxiety and are more difficult to dismiss than the latter (Dent & Salkovskis, 1986; Rachman & DeSilva, 1978; Salkovskis & Harrison, 1984).

Unlike most other Axis I disorders, the symptoms of OCD vary considerably from one patient to the next, sharing only the disturbing nature of the intrusions and the ritualistic efforts to neutralize the obsessions. Many patients report having more than one type of obsession and ritual, often apparently unrelated to each other, although on closer inspection they may share some meaningful thematic content. Most obsessions and compulsions can be grouped into categories, somewhat more easily by type of ritual than type of obsession because of the many variations in the latter category. Most common are checking rituals, which are usually designed to prevent a particular catastrophe like fire, burglary, causing someone harm, embarrassing oneself, or being rejected. Washing rituals serve to remove "contamination" or "dirt" caused by such sources as human or animal body waste, chemicals, or other substances. In many cases washing is thought to prevent a feared disaster such as disease or debilitation from occurring. Repeating compulsions are "magical" rituals in which ordinary actions (such as crossing a threshold or lifting an object) are repeated to prevent harm from occurring (for example, a loved one dying in an accident). Ordering rituals are less common and involve arranging objects to produce symmetry or balance, thereby relieving a feeling of discomfort. Individuals may hoard or collect seemingly useless objects like old magazines and receipts or empty containers to prevent the loss of potentially important information or to avoid waste.

Although subtypes based on obsessive content have been proposed, these have not been widely adopted, probably because they have not been particularly useful in predicting differential treatment response. Instead, obsessive phenomena have been merely described. Goodman et al. (1989) developed a useful Symptom Checklist for this purpose. Their categories include aggressive or harming obsessions, contamination, sexual content, hoarding/saving, religious obsessions, somatic concerns, and a variety of miscellaneous fears about mental images, numbers, and knowing or saying things, among others. From a clinical standpoint, it may be useful to determine the patient's complete list of obsessive and compulsive symptoms, since these can fluctuate over time and may be differentially affected by cognitive and behavioral treatments.

An added component of recent diagnostic criteria for OCD is determination of "poor insight" type, for those who do not recognize the unreasonableness of their behavior (APA, 1994). Historically, OCD was at least partly defined by patients' recognition of the irrationality of obsessions, with those who were convinced of their obsessions considered psychotic or at least "overvalued ideators" (Foa, 1979; Insel & Akiskal, 1986). More recent study indicates that patients range on a continuum from complete awareness (insight) to delusional, with most having at least some insight (e.g., Kozak & Foa, 1994).

6.17.2.2 Differential Diagnosis

According to the *DSM-IV*, OCD must be distinguished from several other conditions that share similar features. For example, obsessions are defined as mental experiences that are not merely excessive worries about real-life problems (e.g., finances, family well-being, health, etc.) that are characteristic of generalized anxiety disorder (GAD) or hypochondriasis. Likewise, obsessions must be different in character from the guilty or depressive ruminations of those with major depression. Preoccupations with food, alcohol, drugs, gambling, and buying are sometimes colloquially termed "obsession" or "compulsion," but are readily distinguishable from obsessive fears of contamination, causing harm, preventing danger, and other anxiety-provoking concerns and rituals. Such appetitive preoccupations are discussed further below, along with other impulsive symptoms and disorders sometimes characterized as "OC Spectrum" disorders.

6.17.3 EPIDEMIOLOGY

Prior to publication of the first Epidemiologic Catchment Area (ECA) study (Karno, Golding, Sorenson, & Burnam, 1988; Robins et al., 1984), the prevalence rates for OCD were believed to be quite low, and were estimated only from rates among psychiatric patient populations. The ECA study was the first to estimate prevalence rates for OCD from community-based samples and using *DSM-III* criteria. Annual prevalence rates ranged from 0.8 to 2.3%. Lifetime prevalence rates ranged from 1.9 to 3.3%, considerably higher than previously thought (Karno et al., 1988; Robins et al.). These rates correspond to similar annual and lifetime prevalence rates reported in Canada (Kolada, Bland, & Newman, 1994), Finland (Vaisaner, 1975), Taiwan (Hwu, Yeh, & Chang, 1989), and Africa (Orly & Wing, 1979). Furthermore, a recent cross-national epidemiological study of OCD (Weissman et al., 1994) reported remarkably similar findings across seven countries (USA, Canada, Puerto Rico, Germany, Taiwan, Korea, & New Zealand), where annual prevalence rates ranged from 1.1 to 1.8, and lifetime prevalence ranged from 1.9 to 2.5.

6.17.3.1 Sex Ratio and Age of Onset

Although early studies found no differences in the frequency of OCD in men and women (Black, 1974; Karno et al., 1988), later ones have shown a slight preponderance of women among OCD patients (Rasmussen & Eisen, 1990; Weissman et al., 1994). A number of studies have noted a preponderance of males with early onset OCD (Bellodi, Sciuto, Diaferia, Ronchi, & Smeraldi, 1992; Flament et al., 1988; Rapoport, 1989; Rasmussen & Eisen, 1990). The mean onset for males ranged from 14 to 19.5 and for females 21.7 to 22 (Bellodi et al., 1992; Rasmussen & Eisen, 1990, 1992a). Therefore during childhood, boys with OCD outnumber girls by up to 2 to 1.

Sixty-five percent of OCD patients developed symptoms prior to age 25 while only 15% developed symptoms after age 35 (Rasmussen & Tsuang, 1986). Thus, the average age of onset appears to be in the late teens or early twenties (Tallis, 1995). The latency from onset to help seeking is estimated at seven to eight years (Yaryura-Tobias & Neziroglu, 1983). Onset of symptoms can be either acute or insidious (Kolada et al., 1994). Some investigators have identified precipitants related to changes in life roles or demands (e.g., pregnancy, childbirth, etc.), with symptoms often focusing on content related to the precipitant (see Diaz, Grush, Sichel, & Cohen , in press). However, at least 40% of OCD patients showed no clear-cut precipitant (Kolada et al., 1994).

6.17.3.2 Clinical Course

In a review of early follow-up studies, Goodwin, Guze, and Robins (1969) concluded that there were three types of clinical course in OCD: a chronic, unremitting course in which 10–15% of patients show deterioration, an episodic course with periods of complete remission, and an episodic course with periods of incomplete remission. Eisen and Steketee's (1997) recent review confirmed some of their conclusions: episodic OCD with full remissions occurs rarely (10–15%), although this percentage increased with longer follow-up periods. Two recent prospective studies of clinical course assessed OCD symptoms using a Psychiatric Rating Scale that allowed determination of whether subjects met diagnostic criteria for OCD, had subclinical symptoms, or remitted entirely. Eisen, Rasmussen, Goodman, et al. (1995) observed that 57% of 51 subjects still met full criteria after two years, although some of these had improved substantially. Of the remainder, 12% had minimal or no symptoms and 31% were partially improved and did not meet diagnostic criteria. Once remitted, 48% later relapsed. A second study of 107 clinic patients followed up to five years after intake showed a slightly better outlook, probably because of a longer treatment follow-up (Steketee, Eisen, Dyck, Warshaw, & Rasmussen, 1996). These patients showed a 22% probability of full remission and 53% for partial remission. Still, as in retrospective studies, more than three-quarters remained symptomatic and at least partially impaired by their symptoms.

A number of unsystematic observations about the clinical course are worthy of note and further study. It has been observed that OCD symptoms can switch (for example, from cleaning to checking or vice versa), but no systematic research has examined this phenomenon (Rasmussen & Eisen, 1992a; Tallis, 1995). Certain features such as mild level of symptoms, atypical symptoms, short duration, and good premorbid personality indicate a favorable prognosis (Kolada et al., 1994). Features suggestive of poor prognosis include being male with early onset of symptoms, symmetry or exactness-related symptoms, symptoms of hopelessness, delusions or hallucinations, family history of OCD, and presence of tics (Eisen & Steketee, 1997; Kolada et al.).

6.17.3.3 Demographic and Cultural Variables

Most studies have not found differences in prevalence of OCD based on race (Hispanic, African-American, whites), religion, or socioeconomic status (Burnam et al., 1987; Karno et al., 1988; Valleni-Basile et al., 1994). However, Karno et al. found OCD to be more common in young, divorced, separated, or unemployed subjects and slightly less common among blacks than whites. Although findings are somewhat conflicting, most studies have concluded that patients with OCD had higher than average levels of intelligence.

Despite approximately equivalent prevalence rates, clients from minority groups have rarely presented for treatment in mental health settings, and in 1991 Neal and Turner noted that no studies had yet examined treatment for OCD in African-Americans. According to recent research, blacks with washing rituals seek assistance more often from medical settings such as dermatology clinics (Friedman, Hatch, Paradis, Popkin, & Shalita, 1995) and may have more severe symptom presentations (Chambless & Williams, 1995). Symptoms of OCD appear to be recognizable across many disparate cultures. The tendency for some people with OCD to show changing symptoms (e.g., checking to cleaning), the wide variety and cultural specificity of symptom expression (e.g., fears of penile shrinkage in China, fears of leprosy in Africa), and the shifts in the content of obsessional fears over time (e.g., from fears of cancer to AIDS-related fears) suggests that OCD is at least partly influenced by cultural factors (e.g., Weissman et al., 1994). Dulaney and Fiske (1994) noted the similarities between OCD rituals and religious or cultural rituals, while other investigators (Greenburg & Witztum, 1994) have found certain religious practices to be associated with symptom expression in OCD (Okasha, Saad, Khalil, Dawla, & Seif, 1994). Thus, there is little evidence that culture is important in the development of OCD, but it may well influence the way the disorder is expressed.

6.17.4 COMORBIDITY AND RELATED DISORDERS

6.17.4.1 Axis I Disorders

Rasmussen and Eisen (1990) reported that nearly 60% of their OCD clinic patients had at least one other disorder, and some estimates are even higher (e.g., Lucey, Butcher, Clare, & Dinan, 1994). A wide variety of Axis I disorders appear to be associated with OCD, including anxiety disorders, depression, alcohol abuse (dependence), eating disorders, Tourette's syndrome, body dysmorphic disorder (BDD), hypochondriasis, and schizophrenia. Comorbidity of OCD with other anxiety disorders is quite high, ranging from 25–60% (Weissman et al., 1994). The highest frequencies are evident for specific phobias (Karno et al., 1988), with social phobia and panic disorder co-occurring in 10–50% of samples (see Steketee, Henninger, & Pollard, in press). Interestingly, GAD, which shares a ruminative focus with OCD, occurred infrequently among those with primary OCD (Turner, Beidel, & Stanley, 1992). Family studies have also suggested a shared genetic vulnerability with other anxiety disorders (Black, Noyes, Pfohl, Goldstein, & Blum, 1993).

There is strong evidence for a shared vulnerability for depression as well, with various studies indicating concurrent prevalence rates of 12–80% (Steketee et al., in press). Most studies concur that at least one-third of patients with OCD report histories of clinical depression (e.g., Crino & Andrews, 1996; Weissman et al., 1994), although 25–33% do not report depression (Rassmussen & Eisen, 1992b; Rasmussen & Tsuang, 1986). Interestingly, recent evidence indicates that the frequency of bipolar disorder in OCD is similar to that of major depression in this group (Kruger, Cooke, Hasey, Jorna, & Persad, 1995). The frequency of affective disturbance in OCD, together with genetic and treatment response findings, have led some to question whether OCD might better be classified as a variant of depression. Crucial to this issue is whether the depression which accompanies OCD is primary or secondary to OCD. Most patients report that the onset of depressive symptoms occurred after the onset of OCD (e.g., Rasmussen & Eisen, 1992b; Wilner, Reich, Robins, Fishman, & van Doren, 1976), and several investigators have found that successful treatment of OCD resulted in the reduction of depressive symptoms (e.g., Foa, Steketee, Grayson, Turner, & Latimer, 1984; Yaryura-Tobias & Neziroglu, 1983). These findings, as well as the centrality of anxiety in obsessive thinking and the comorbidity with anxiety disorders, argue for classification of OCD as an anxiety rather than depressive disorder.

Despite a wide range in the degree of insight that accompanies obsessions, OCD is relatively rarely accompanied by schizophrenia (Jenike, 1990; Tallis, 1995), although some research suggests a link (Yaryura-Tobias, Campisi, McKay, & Neziroglu, 1995). Furthermore, Enright (1996) proposed that an information-processing view could account for both disorders. Schizotypy is a normal personality dimension which ranges from healthy to schizophrenic and is proposed as the continuum which links OCD to schizophrenia. Enright and Beech (1990) observed that OCD patients had more schizotypal traits than patients with other anxiety disorders (see also Baer & Jenike, 1992), and, like schizotypal and schizophrenic subjects, had less cognitive inhibition. They proposed that obsessional thoughts result from a failure in the cognitive inhibition of associations to ongoing stimulation. Further research is necessary in order to examine Enright's hypothesis more fully.

A number of impulse control disorders have been found to be comorbid with OCD or to share common features (Tynes, White, & Steketee, 1990) which has led to their labeling as "OC Spectrum Disorders." These include Tourette's syndrome, trichotillomania, kleptomania, and exhibitionism. Many studies have shown an association of OCD to Tourette's syndrome (e.g., Leckman & Chittenden, 1990; Pauls, 1990; Robertson, 1991), as well as to other tic disorders and Sydenham's chorea (Rapoport, Swedo, & Leonard, 1992). In view of observations that one form of Tourette's may be OCD-related and some OCD cases are Tourette's-related (Leckman & Chittenden, 1990), OCD and Tourette's may be different expressions of a similar underlying genetic abnormality (Pauls & Leckman, 1986; Pauls, Towbin, Leckman, et al., 1986), for example, in basal ganglia-frontal cortex pathways (Rapoport et al., 1992). There are also reports of associations between OCD and kleptomania (McElroy, Hudson, Pope, & Keck, 1991), and exhibitionism (Snaith, Baugh, Clayden, Husain, & Sipple, 1983). Although relatively little empirical research has been done examining these relationships, enough suggestive evidence exists to warrant a closer examination.

DSM-IV diagnostic criteria rule out a diagnosis of OCD if the content of the obsessions or compulsions focus on the primary symptoms of several other disorders (e.g., eating disorders, body dysmorphic disorder, hypochondriasis, even if all other inclusion criteria are met. However, the observed similarity of food-related thoughts in eating disorders to obsessions has resulted in a substantial body of research on the relationship between OCD and eating disorders. Beyond similarities in the nature of the symptoms, this research suggests that OCD symptoms are more prevalent in eating disorder patients than in controls, and that eating disorders are found at a higher rate in OCD (8–11%) than in other disorders (Formea & Burns, 1995; Hsu, Kaye, & Weltzin, 1993; Kaye et al., 1992). Also suggestive is the finding that dieting and weight loss can cause changes in serotonergic activity (Goodwin, Fairburn, & Cowen, 1987). Furthermore, there is evidence that behavioral treatments (exposure and response prevention) and serotonergic reuptake inhibitors (SRIs), both effective in treating OCD, are similarly useful for eating disorders (Hsu et al., 1993; Rosen & Leitenberg, 1982). Rothenberg (1986) has suggested that eating disorders are a modern day variant of OCD, and that cultural pressures for thinness in Western societies lead young women vulnerable to OCD to anorexia and bulimia. This reasoning is consistent with Weissman et al's. (1994) proposal that cultural influences partly determine symptom presentation.

Similarly, body dysmorphic disorder has been linked to OCD. BDD is characterized by excessive preoccupation with a presumed defect in appearance. The obsessional nature of thoughts about appearance and anxiety-reducing behaviors (e.g., mirror checking, asking for reassurance) resemble classical OCD symptoms. Simeon, Hollander, Stein, Cohen, and Aronowitz (1995) found that 12% of OCD patients were comorbid for BDD during their lifetime, and Neziroglu and Yaryura-Tobias (1993) have proposed that BDD may actually be a form of OCD. Consistent with this notion, Hollander, Liebowitz, Winchel, Klumker, and Klein (1989) found that all five BDD patients in a clinical series responded to SRIs. The most apparent difference was that BDD patients showed less insight into their illness and may suffer from overvalued ideas rather than obsessions (Vitiello & de Leon, 1990). Nonetheless, in reviewing the limited evidence, Hollander, Neville, Frenkel, Josephson, and Liebowitz (1992) suggested that considering BDD a subgroup of OCD may be useful.

Hypochondriasis is characterized by obsessive-like fears of having a serious disease. The similarities between hypochondriacal and obsessional symptoms has been noted (Fallon, Javitch, Hollander, & Liebowitz, 1991; Tynes et al., 1990), as has the frequency of somatic obsessions in OCD patients (Rasmussen & Tsuang, 1986). In one of the few empirical investigations on this question, Barsky, Wyshak, and Klerman (1986) found comorbid OCD in 9.5% of 42 hypochondriacal patients, while only 2.6% of a nonhypochondriacal control group had OCD. These findings indicate some association of the two disorders.

6.17.4.2 Axis II Disorders

The picture of comorbidity with personality disorders (PD) is somewhat more confused. While it is clear that personality disorders occur frequently in conjunction with OCD, the specific type of personality disorder most often associated with OCD has varied substantially from study to study. This is probably a result of relatively small sample sizes and personality assessment instruments with lower reliability than those used for Axis I disorders. Most studies of Axis II comorbidity have found that over half of patients with OCD also have at least one diagnosable personality disorder (Baer & Jenike, 1992; Cassano, Del Buono, & Catapano, 1993). Along with obsessive-compulsive personality disorder (OCPD), the most frequently diagnosed personality disorders among patients with OCD are avoidant, dependent, histrionic, passive-aggressive, and schizotypal personality disorder. Pfohl and Blum's (1991) conclusion regarding the frequency of PD occurrence in those with OCD may be the most accurate reflection of current knowledge: most patients with OCD do not have comorbid OCPD, and for those who have a personality disorder, it is just as likely to be one other than OCPD. Interesting, no studies have shown antisocial personality disorder to occur frequently in OCD, and Mavissakalian, Hamann, and Jones (1990a) found it to be the least frequent. This finding is consistent with observations that patients with OCD generally show excessive responsibility (see below), a trait quite incompatible with antisocial behavior.

The issue of whether PD is the primary or secondary disorder when comorbid with OCD has rarely been addressed. However, findings such as those by Mavissakalian, Hamann, and Jones (1990b) that the number of personality disorder diagnoses, and scores on personality disorder measures, declined following successful treatment for OCD indicate that such traits may not be intractable patterns of behavior. In particular, avoidant and dependent traits commonly associated with other anxiety disorders may merely reflect a general vulnerability to anxiety and possibly depression, both being responsive to focused treatments. However, some traits such as passive-aggressive behaviors, borderline and schizotypal features may be problematic for treatment outcome (e.g., Baer & Jenike, 1992; Steketee, 1990).

6.17.5 OCD PATIENT CHARACTERISTICS

6.17.5.1 Family Factors in OCD

Several studies report that the celibacy rate, especially among males with OCD who have early onset, is higher than that found in the general population (cf Eisen & Steketee, 1997). Among those who are married, marital dysfunction has been observed, but overall marital satisfaction among clinical patients does not differ from the general population (e.g., Riggs, Hiss, & Foa, 1992). Family members (spouses and parents) often become quite involved in patients' symptoms, especially in performance of rituals and taking over tasks that are difficult or avoided (Calvocoressi et al., 1995; Shafran, Ralph, & Tallis, 1995). They often modify routines to adapt to OC symptoms, sometimes to the extent of restructuring household arrangements altogether. Greater family involvement symptoms was significantly correlated with family dysfunction and negative attitudes toward the patient (Calvocoressi et al.). However, the marital relationships of patients with OCD are no worse than those of the general population (Riggs et al., 1992). Family responses to OCD have been observed to span the range from accommodating to antagonistic toward patients (Livingston-Van Noppen, Rasmussen, Eisen, & McCartney, 1990). Including family members in assessment is recommended, since they may provide important information not volunteered by the patient (Van Noppen, Steketee, McCorkle, & Pato, 1996).

With regard to etiological factors, a number of characteristics of parents have been hypothesized to play a role in the development of OCD. Rachman (1976a) suggested that among individuals with a personal vulnerability (i.e., oversensitivity to criticism), certain parental traits may lead to OCD symptoms. He hypothesized that parents of OCD cleaners are more overcontrolling and overprotective and may model excessive cleaning behaviors. Parents of checkers were hypothesized to set high standards for their children, be overcontrolling and overcritical, as well as modeling meticulousness. Other investigations have observed or speculated on similar themes in the parents of OCD patients, including demanding or critical attitudes (Clark & Bolton, 1985; Hoover & Insel, 1984; Kringlen, 1965; Steketee, Grayson, & Foa, 1985); overprotectiveness (Hafner, 1988; Honjo et al., 1989); perfectionism (Allsopp & Verduyn, 1990; Honjo et al., 1989; Hoover & Insel, 1984; Lo, 1967; Rasmussen & Tsuang, 1986), and rejecting attitudes (Emmelkamp, Hoekstra, & Visser, 1985). However, systematic research on hypothesized differences between the parents of OCD patients and controls has been limited.

Merkel, Pollard, Wiener, and Staebler (1993) found that OCD patients perceived their mothers to be more overprotective than did depressed patients. Contrary to expectation, however, OCD patients described their fathers as less demanding than did panic disorder patients. Chambless, Gillis, Steketee, and Tran's (1996) study of parental warmth and overprotection in OCD and agoraphobia indicated that parents' and patients' recollections of parental behavior did not agree. Patients reported that their parents most often raised them using affectionless control, whereas parents most often rated themselves as having provided optimal parenting. Reports of poorer parenting were associated with worse social adjustment and higher levels of anxious personality disorder characteristics. However, the lack of a normative sample limits conclusions about the relevance of parenting ratings to obsessive symptomatology. Studying volunteers, Frost, Steketee, Cohn, and Griess (1994) found that subjects with subclinical OCD described their parents as more overprotective than nonobsessive-compulsives. They also found some evidence that both parents of the subclinical OCD group were more risk-aversive, and fathers were more critical and perfectionistic than fathers of control subjects. In a related vein, Hibbs et al. (1993) and Hibbs, Hamburg, Kruesi, and Lenane (1993) observed that families of children with OCD had higher levels of expressed emotion (criticism and overinvolvement) than families of control subjects (82% vs. 41%).

While the nature and characteristics of the families of OCD patients are far from clear, there is enough clinical observation and preliminary evidence to hypothesize that the parents of people who develop OCD are more likely to show a constellation of behaviors, including perfectionism, overprotectiveness, overcritical and demanding attitudes, and high levels of risk avoidance. Once further research has established that these characteristics are more prominent in the families of OCD patients than in controls, the question of their role in the development of the disorder can be addressed.

6.17.5.2 Personality and Cognitive Characteristics

Much of the early description of the obsessive-compulsive personality was tied to psychodynamic assumptions of the role of the anal personality in both OCPD and OCD, with little distinction made between these two conditions. The orderliness, parsimony, and obstinacy thought to typify people with OCD were expanded into more specific personality traits such as those articulated by Pollack (1987): "procrastination, indecision, self-doubting, driven by obligations and responsibilities, attempting to attain order and perfection, bound by routines, uncomfortable and avoidant of novelty and change, interpersonally formal and even cold, authoritarian and controlling, autocratic, critical, and punitive" (pp. 249–250). Although some of these latter traits better describe OCPD, others have recently been viewed as characteristic cognitive aspects of OCD.

A host of personality/cognitive features are closely linked to OCD (see Reed, 1985; Tallis, 1995). Prominent among these are overestimation of risk, exaggerated responsibility and guilt, beliefs about the need to control thoughts, fusion of thought and action (thinking something makes it so), perfectionism, uncertainty and doubt, and intolerance for emotional discomfort. These domains were also identified by a group of international researchers attempting to develop a coherent approach to the assessment of cognitions in OCD (International OCD Cognitions Working Group, 1996). The group noted that many of these domains overlap considerably. Using an expert consensus strategy, they selected a subset of five areas and defined these in order to generate items for a self-report measure of these domains. In discussing the several cognitive domains listed below that may be common features of OCD, we include the expert consensus definitions of the working group where relevant.

6.17.5.2.1 Overestimation of risk

It has long been noted that patients with OCD exaggerate the probability and severity of bad outcomes (Carr, 1971, 1974). Clinical (Rasmussen & Eisen, 1989) as well as empirical (Steketee & Frost, 1994) evidence supports the hypothesis that people with OCD are risk-aversive. An expert working group defined threat overestimation as "exaggeration of the probability or severity of harm believed to result from or follow intrusive internal experiences" (Obsessive Compulsive Cognitions Working Group 1997).

6.17.5.2.2 Responsibility

Overimportance assigned to intrusive thoughts and an exaggerated sense of responsibility for harm coming to self or others are closely related cognitive features widely noted in the OCD literature (Freeston, Rhéaume, & Ladouceur, 1996; Rachman, 1993). Salkovskis (1985) argued that exaggerated responsibility is central to the symptoms of OCD, and empirical literature supports its importance in OCD (cf Lopatka & Rachman, 1995; Rachman, 1993; Salkovskis, 1985). Closely related to responsibility is the emotional experience of guilt. People with OCD have been found to score significantly higher than other groups on measures of guilt (Frost, Heimberg, Holt, Mattia, & Neubauer, 1993; Niler & Beck, 1989; Steketee, Quay, & White, 1991). Salkovskis' and others' definition of responsibility adopted by the working group was "the belief that one has power which is pivotal to bring about or prevent subjectively crucial negative outcomes. These outcomes are perceived as essential to prevent. They may be actual, that is, having consequences in the real world, and/or at a moral level" (Salkovskis, Rachman, Ladouceur, & Freeston, 1992).

6.17.5.2.3 Controllability of thoughts

Another important cognitive feature of OCD is disruption in the control of thoughts. Clark and Purdon (1993) suggested that in normal cognitive processing, irrelevant and intrusive thoughts are simply ignored, whereas individuals with OCD attend to them, consider them important, and attempt to suppress them. The failure of these efforts at suppression results in sensitization and vigilance to all thoughts similar to the intrusion. The cycle of attention to intrusions followed by attempts at suppression are hypothesized to escalate to an obsessional pattern (Salkovskis & Campbell, 1994; Wegner, 1989). The cognition working group identified a domain of "need for control" and defined this as "overvaluation of the importance of exerting complete control over intrusive thoughts, images, and impulses, and the belief that this is both possible and desirable." Dimensions of the need to control were considered to include tracking mental events and hypervigilance; moral consequences—control as a virtue; psychological and behavioral consequences—insanity, decreased ability to function; and immediate efficiency and future success of control efforts.

6.17.5.2.4 Overimportance of thoughts

The reasons for the overimportance of intrusive thoughts and the perceived necessity for controlling them may lie in a belief about the meaning of these thoughts. Rachman and others proposed that people with OCD tend to believe that simply having a thought, particularly an unwanted and objectionable thought, is morally equivalent to engaging in the objectionable act (Rachman, Thordarson, Shafran, & Woody, 1995). That is, thinking something morally reprehensible is just as bad as doing it. Evidence for such "thought-action fusion" (TAF) can be found in the perception of OCD patients that imagined negative events are more likely actually to occur (Rachman, Shafran, et al., 1995). Such beliefs that thoughts can influence the probability of occurrence of negative events may be a part of an exaggerated sense of responsibility (for negative thoughts and events) by people with OCD. Recent attempts to measure and study TAF support the importance of this construct (Rachman, Shafran, et al., 1995; Shafran, Thordarson, & Rachman, 1996). The Obsessive Compulsive Cognitions Working Group (OCCWG, 1997) identified "overimportance of thoughts" as a central feature of OCD and defined this as a "belief that the presence of an intrusive thought per se gives it significance or means that it is important. This includes concepts of thought/action fusion, Cartesian reasoning, and magical thinking."

6.17.5.2.5 Tolerance for ambiguity

Part of the construct of perfectionism (Frost, Marten, Lahart, & Rosenblate, 1990), one that is perhaps more uniquely tied to OCD, is the experience of doubt about the veracity of experience and the quality of one's actions. Although not part of the formal diagnostic criteria, doubting is a hallmark of OCD (Reed, 1985). Doubt about the validity of experience can leave one uncertain about whether actions are appropriate or adequate to ward off danger. The need for absolute certainty or the inability to tolerate uncertainty is also a commonly noted feature of OCD (Kozak, Foa, & McCarthy, 1987; Rasmussen & Eisen, 1990). Guidano and Liotti (1983) suggested that doubt stems from a belief that every situation has a perfect solution and the person with OCD will not feel comfortable unless that perfect solution is found. Others have suggested that the need for certainty maintains ritualistic behaviors which must be repeated because certainty has not been achieved (Beech & Liddell, 1974). Such doubt is believed to be the root of the indecision seen in people with obsessive-compulsive tendencies (Frost & Shows, 1993). The working group identified intolerance of ambiguity as encompassing "beliefs about the necessity of being certain, about the capacity to cope with unpredictable change, and about adequate functioning in situations which are inherently ambiguous."

6.17.5.3 Information/Cognitive Processing in OCD

Quite apart from personality traits and beliefs which characterize OCD, several information-processing capabilities have been hypothesized to distinguish OCD patients from nonpatients. These processes involve memory, categorization, and attention. Reed (1977) suggested that a "pathologically faulty memory" was a central feature of OCD. Patients with OCD may suffer from deficits in memory for actions (especially among those with checking rituals, general memory, confidence in memory functioning, and reality monitoring (distinguishing actual from imagined actions). For nonclinical compulsive checkers, several studies have established the presence of deficits in memory for discrete actions performed (e.g., Rubenstein, Peynircioglu, Chambless, & Pigott, 1993; Sher, Frost, Kushner, Crews, & Alexander, 1989; Sher, Frost, & Otto, 1983). However, among clinical patients, this finding is less consistent, with one study supportive and another failing to replicate (see Tallis, 1995). With respect to general memory deficits, similar findings have emerged from neuropsychological studies of OCD. Nonclinical subjects showed poorer overall memory functioning (e.g., Sher et al., 1989), whereas findings for clinical patients were more mixed, although most studies reported poorer memory functioning, especially visual memory (e.g., Boone, Ananth, Philpott, Kaur, & Djenderedjian, 1991; Christensen, Kim, Dysken, & Hoover, 1992; Martinot et al., 1990; for an exception see Constans, Foa, Franklin, & Matthews, 1995). Research has consistently shown lowered confidence in memory capacity but not worse reality monitoring (Brown, Kossyln, Breiter, Baer, & Jenike 1994; Constans et al., 1995; McNally & Kohlbeck, 1993; Sher et al., 1983).

Consistent with hypotheses about memory dysfunction in OCD, Reed (1985) also argued that such patients fail to categorize and integrate information, leading to underinclusive categorization in which many small categories are generated with narrow boundaries and overspecified rules for category membership. Persons and Foa (1984) found some empirical support for this notion, and Frost and Hartl (1996) have described this as a nettlesome problem for compulsive hoarders. Because of a general failure to recognize reasonable boundaries for categories and experiences, OCD patients create artificial structures to govern their behavior. Thus, rituals, particularly checking rituals, are attempts to create an artificial structure to determine the end of a sequence of behaviors.

Other theorists have emphasized deficits in attentional processing in OCD. Enright and Beech (1990, 1993a, 1993b) proposed an information-processing theory of OCD which focuses on deficits in selective attention. They hypothesized that OCD patients fail to adequately inhibit irrelevant stimuli during normal cognitive processing, interfering with their focus on relevant stimuli. Consequently, processing of ordinary information requires a more conscious and effortful strategy, and suppression of irrelevant or unwanted thoughts is more difficult. The same cognitive inhibition deficit is hypothesized to characterize schizophrenia and schizotypal personality disorder (Enright, 1996). Enright and Beech (1993a, 1993b) report several studies which support their hypotheses using a negative priming paradigm.

Another approach to studying attentional processes in OCD has been to examine the processing of fear-relevant information, mainly using a Stroop task in which subjects observe fearful and nonfearful words presented in different colors, and are asked to name the color of the word, thereby inhibiting processing of its meaning. Fearful word meanings should be harder to inhibit and therefore take longer. Consistent with this hypothesis, Foa, Ilai, McCarthy, Shoyer and Murdock (1993) found that OCD washers took longer to name contamination words than neutral words, and that patients with other types of fears did not show such an effect, supporting the specificity of the processing effect. Lavy, van Oppen, and van den Hout (1994) found that OCD subjects selectively attended to negative OC-related words (e.g., disease, disaster) but did not show an attentional bias to positive ones (e.g., clean, precise). Of considerable interest is Foa and McNally's (1986) observation that after successful treatment OCD patients no longer showed attentional bias toward contamination items in a dichotic listening task.

The above research findings provide some confirmation of OCD deficits in memory for actions and in general memory. Decreased confidence in memory functioning is evident in clinical samples, but not problems in distinguishing actual from imagined actions. Problems with overspecification in categorization have been observed, and OCD patients also show problems in inhibiting attention to irrelevant information and in attending to relevant ones. Specific causes for these difficulties will require further research.

6.17.6 THEORETICAL MODELS AND TREATMENTS FOR OCD

The review presented below includes three major theoretical models for the development and maintenance of OCD, followed by treatment methods that are generally derived from these models. We then present evidence for their effectiveness. We begin with behavioral theories and treatments, followed by a discussion of newer cognitive models and derived treatments, and biological models and pharmacological treatments for OCD. In juxtaposing models with treatment methods, some anomalies in the practical application of methods derived from theory will be apparent. In the case of biological theories, the discovery of effective treatments (serotonergic reuptake inhibitors, SRIs) have partly driven speculations about explanatory models such as the role of serotonin. At the end of this section, we examine combined behavioral and pharmacological treatments and follow this with an effort to determine the comparative efficacy of behavioral, cognitive, and pharmacological treatments and their combinations.

6.17.6.1 Behavioral Models for OCD

Early psychological conceptualizations of the development of OCD were based mainly on psychodynamic models. However, although treatments derived from these models lead to some improvement, more for outpatients than inpatients, average rates of approximately 60% improved were not considered impressive (see Cawley, 1974). Not surprisingly, OCD gained a reputation as intractable (e.g., Coryell, 1981). Early behavioral treatments (thought stopping, aversion therapy) based on contingent reinforcement and punishment models were also successful for only a limited group of patients, often fewer than 50% (Emmelkamp & Kwee, 1977; Kenny, Mowbray, & Lalani, 1978; Stern, 1978). Interestingly, early efforts to utilize conditioning models alone (systematic desensitization, paradoxical intention, repeatedly verbalizing obsessive thoughts) improved the situation only slightly (Beech & Vaughn, 1978; Emmelkamp & Kwee, 1977; Solyom, Garza-Perez, Ledwidge, & Solyom, 1972). In the late 1960s and early 1970s newly developed intensive behavioral treatments that incorporated both conditioning models and negative reinforcement notions showed considerable promise. Labeled exposure and response (ritual) prevention (ERP), these strategies were derived from learning theory models discussed below.

The first part of a two-stage theory for acquiring and maintaining fear and avoidance behavior posits that an otherwise neutral event acquires the capacity to provoke fear because of its pairing with an aversive experience, much as a dog phobia might develop from being bitten (Dollard & Miller, 1950; Mowrer, 1960). Evidence supporting this fear acquisition process is inadequate, since many patients cannot recall conditioning experiences associated with symptom onset, and although onset often follows very stressful life events, it rarely does so immediately, as postulated by the traumatic onset theory (e.g., Rachman & Wilson, 1980). A more likely explanation is that stressful events sensitize some individuals to cues that have an innate tendency to elicit fear, were learned during early traumatic experiences, or have special cultural significance (Rachman, 1971; Teasdale, 1974; Watts, 1971). Observational or informational learning may also account for some OCD onsets (Foa & Kozak, 1985; Rachman, 1977), particularly when clients report that their symptoms resemble their parents' behavior. For example, hoarding rituals may mimic a cluttered home resulting from excessive saving by a parent of unneeded but "potentially useful" objects.

In the second stage of the two-factor model, any actions (escape or avoidance behavior, compulsions) that relieve obsessive anxiety/discomfort are negatively reinforced because they result in reduction of discomfort. Their demonstrated ability to terminate unpleasant experiences renders them very likely to be repeated in future situations. As Foa and Kozak (1985) have noted, both external cues (objects or situations) and internal triggers (thoughts, images, or impulses) can produce obsessive discomfort. Many of these triggers (e.g., locking the front door) cannot be avoided and therefore passive avoidance behaviors which enable phobics to manage their fears are often insufficient to control anxiety for those with OCD. More active compulsions are needed to prevent harm or restore a feeling of safety (Rachman, 1976a).

Substantial evidence supports a behavioral view of OCD as a functional anxiety-based disorder in which obsessions increase discomfort and compulsions reduce it. In the laboratory, production of obsessive thoughts increased heart rate and skin conductance more than neutral thoughts (e.g., Boulougouris, Rabavilas, & Stefanis, 1977), and contact with contaminants also increased subjective and physiological anxiety reactions (Hodgson & Rachman, 1972; Hornsveld, Kraaimaat, & van Dam-Baggen, 1979). Corresponding to the second stage of the behavioral theory, completing compulsions reduced anxiety in most instances (e.g., Hodgson & Rachman, 1972; Hornsveld et al., 1979). Occasionally reported increases in discomfort following compulsions appear to be frustration reactions to having to complete time-consuming unwanted behaviors. Thus, evidence supports a two-stage behavioral model characterizing the maintenance of OCD symptoms, but it does not account for many instances of onset unless other explanatory variables are added.

6.17.6.2 Behavioral Treatments for OCD

Treatment strategies that follow logically from the model attempt to disconnect obsessions from their associated discomfort (deconditioning), rendering them more like intrusions in normal samples, and to eliminate rituals that reinforce obsessive fears. In an elaboration on this two-factor model, Foa and Kozak (1985) concurred with Peter Lang's theories that fear or anxiety could be viewed as a memory network containing representations of concrete stimuli, associated physiological responses, and meanings assigned to these (cognitive elements). Correction of all three components would be necessary to eliminate fear, although exposure to at least one part of the network might evoke other elements. Following from both models, behavioral intervention for obsessions and chronic rituals involves exposure to overt and covert cues that provoke obsessions and blocking of rituals (response prevention) to prevent them from prematurely reducing obsessive fears and thus interfering with habituation of the negative mood generated by obsessions. This ERP treatment has been widely studied and found highly effective, although as for medication treatment, residual symptoms and treatment refractory cases plague the field. Salient research on ERP and its components are described below.

Considerable improvement in effectiveness of treatments came with the systematic application of prolonged exposure to obsessions and blocking or prevention of compulsions. Meyer and his colleagues are credited with development of effective ERP treatment with hospital patients who feared contamination and hand washing rituals (Meyer & Levy, 1973; Meyer, Levy, & Schnurer, 1974). Using a strict and intensive program of daily direct contact with contaminants and complete prevention of rituals (turning off plumbing in patients' rooms and having nurses observe all washing), these investigators reported that 10 of their 15 patients were much improved or symptom-free, and the remaining five were moderately improved. Only two relapsed after five to six years. Not surprisingly, such remarkable results led to many investigations of ERP in inpatient and outpatient settings in several countries. To date, approximately 30 open trials and controlled studies representing over 600 clients with OCD have reported good outcomes with variants of ERP. Tables detailing the outcome of these studies are available in a review by Steketee and Shapiro (1993). Highlights of findings from these studies along with their clinical implications, particularly for variations of ERP, are discussed below.

6.17.6.2.1 Degree of improvement from ERP

A series of early studies of inpatients by Rachman, Marks, and colleagues at the Maudsley Hospital in London indicated that 15 sessions of exposure and blocking over a threec-week period was considerably more effective than relaxation training, and overall effectiveness was excellent even two years later (Marks, Hodgson, & Rachman, 1975). Seventy-five percent of patients were responsive to ERP, and the majority showed substantial change. This improvement rate has been replicated across numerous studies using 10–20 sessions of treatment. On average, 85% of clients were at least "improved" immediately after treatment, and about 55% fell into the "much improved" or "very much improved" categories, implying that target symptoms improved by more than half (Steketee, 1993). At follow-up, improvement rates remained high, averaging about 75%, and 50% in the "much improved" or "very much improved" groups. Thus, results were largely maintained with some relapse evident and some clients needing additional therapy (Emmelkamp, Visser, & Hoekstra, 1988; Foa & Goldstein, 1978).

With regard to symptom improvement, the most positive results were evident on target ratings of treated obsessions and compulsions, where the average degree of benefit immediately after ERP ranged from 40%–75% (Steketee & Shapiro, 1993). On other standardized self-report measures, the level of improvement was slightly lower. At follow-ups ranging from three months to six years, treatment gains were only slightly different across studies, falling in the 45–70% range for target symptoms, and averaging 50% improvement for questionnaire measures. The consistency of ERP results and the degree of benefit across multiple treatment sites and countries is quite impressive, clearly indicating that exposure and response prevention is an effective treatment for OCD symptoms. However, the above summary does not address the question of how many of these treated patients no longer meet criteria for the diagnosis of OCD or no longer require intervention for their symptoms. Some more recent investigations have assessed improvement using the standardized Yale–Brown Obsessive Compulsive Scale (YBOCS) in which scores correspond closely to diagnostic categorizations (16 and above usually meets criteria for OCD). Outcomes of studies using the YBOCS to assess ERP treatment are presented in Table 1.

6.17.6.2.2 Specific effects of exposure and response prevention

Examining the separate effects of exposure and response prevention on obsessions and compulsions, Foa and colleagues, as well as other investigators, found support for the behavioral model from which ERP is derived. In their first trial with 21 patients (Foa & Goldstein, 1978), 86% had stopped ritualizing after treatment, but only 57% improved substantially on obsessions, suggesting that compulsions responded more to ERP than obsessions. According to behavioral theory, exposure should particularly reduce anxiety associated with obsessions, whereas prevention of ritualistic behavior should influence rituals more than obsessions. This dual hypothesis was supported in multiple case studies of OCD patients (Mills, Agras, Barlow, & Mills, 1973; Turner, Hersen, Bellack, Andrasik, & Capparell, 1980), as well as in group trials. Both interventions delivered separately reduced obsessions and rituals, but exposure affected subjective anxiety more than rituals, and response prevention reduced rituals more than obsessions. The addition of the missing component led to maximum improvement in both symptoms (Foa et al., 1984; Foa, Steketee, & Milby, 1980). These findings support the suggestion that exposure and prevention of rituals operate by separate mechanisms.

6.17.6.2.3 Processes during exposure

Foa and colleagues have suggested that effective ERP relies on subjective and physiological processes activated by exposure and blocking, that reflect the processing of emotional information pertinent to the obsessive symptoms. These processes include activation of obsessive anxiety (reactivity) and gradual decrease (habituation) of these reactions during exposure, as well as across exposure sessions (Foa & Kozak, 1986). Habituation during direct imagined exposure, and habituation across sessions, have been demonstrated (Grayson, Foa, & Steketee, 1982; Shahar & Marks, 1980) and associated with more change in therapy (Foa, Steketee, Grayson, & Doppelt, 1983; Kozak, Foa, & Steketee, 1988). Habituation rates may vary as a function of the intensity of arousal (Foa et al., 1983; Kozak et al., 1988). Therefore clinicians can use intensity of arousal and habituation rates to judge the course of therapy and make adjustments in the type and length of exposure necessary. Findings by Grayson and colleagues regarding the benefits of attention-focusing versus distraction from exposure (e.g., Grayson, Steketee, & Foa, 1986), suggest that in standard clinical practice therapists are advised to ask clients to concentrate on their fears during exposure, and avoid distracting conversation that might interfere with the processing of fearful information.

6.17.6.2.4 Problems in the treatment of pure obsessive symptoms

Early evidence indicated that patients with obsessions but no overt compulsions tended to have poorer outcome than those with clear rituals (e.g., Emmelkamp & Kwee, 1977; Rachman, 1976b). A possible reason for their failure to respond consistently to exposure treatment is that obsessions alternated with undetected and untreated mental rituals (see Salkovskis & Westbrook, 1989; Steketee & Foa, 1985). In such cases, prolonged exposure might actually have strengthened mental rituals by repeatedly provoking them and thereby preventing habituation of obsessions, consistent with Salkovskis and Westbrook's (1989) observation that following an obsessive thought with a "neutralizing" one (mental ritual) actually *increased* discomfort. According to behavioral theories of

OCD, effective treatment would require that exposure be applied only to obsessive thoughts, and mental compulsions should be blocked (e.g., by thought stopping, distraction, or substitution). Several researchers have demonstrated the success of such a strategy especially using uninterrupted audiotaped exposures to narrated obsessions (e.g., Rachman, 1976c; Salkovskis & Westbrook, 1989).

6.17.6.2.5 Variants in delivery of ERP

Several variations on ERP procedures have been studied. Emmelkamp and colleagues in Holland reported positive effects for a home-based therapy using ERP without the careful monitoring of *in vivo* exposure and rituals carried out with hospitalized patients (Boersma, Den Hengst, Dekker, & Emmelkamp, 1976). In a controlled study, therapist-directed exposure did not improve on the outcome of self-controlled treatment (Emmelkamp, van den Heuvell, Ruphan, & Sanderman, 1989) and the latter may have produced more durable gains (Emmelkamp & Kraanen, 1977). In Kirk's (1983) efforts to apply ERP to consecutive patients in an outpatient clinic setting, therapists relied more on homework assignments than on accompanied direct practice to achieve gains, unless progress required the therapist's presence. Correspondingly, in a third of cases, relatives and friends played a significant role in assisting in treatment. The deliberate involvement of relatives in behavioral treatment is described in more detail below.

Dutch investigators also reported that 10 sessions of treatment was too short, since on average clients required an additional 15 treatment sessions during follow-up (Emmelkamp, van der Helm, van Zanten, & Plochg, 1980). Foa and colleagues concurred, as evident from the expansion of their program from 10 sessions to 15 sessions plus home visits (see Foa & Goldstein, 1978; Steketee & Foa, 1985). Rachman and colleagues observed that 30 sessions led to somewhat more improvement than 15 sessions, but the gains were not substantial (Rachman et al., 1979). However, in a clinical study, Kirk (1983) obtained good outcome despite the fact that half of the patients attended 10 or fewer sessions directed specifically at the OCD symptoms. However, it may be that Kirk's clinic patients would have benefited from more sessions but could not afford the time or money to do so. In research trials, frequency of sessions has not made a difference in outcome (Emmelkamp et al., 1989), and examination of the outcome of studies that used different frequencies of treatment produced the same findings (Steketee & Shapiro, 1993).

Direct (*in vivo*) exposure has been delivered in nearly all studies of ERP, but some studies have also included imagined exposure or have compared these variants. Findings indicate that direct exposure is needed (Rabavilas, Boulougouris, & Stefanis, 1976) and that imagined exposure may confer added benefits, particularly at follow-up, for those patients for whom catastrophic outcomes are salient components of their obsessions (e.g., Foa, Steketee, & Grayson, 1985). From the above findings it appears that 10–20 sessions of self- or therapist-controlled ERP applied one to five times per week provides an adequate trial of ERP for most patients with OCD. Longer direct exposure sessions or assignments (generally about an hour) are more advisable than short exposures (Rabavilas et al., 1976) to permit reduction in their obsessive anxiety. Imagined exposure may be added for patients with problematic catastrophic fears.

6.17.6.2.6 Group treatment for OCD

Group interventions for delivering ERP have been examined in several studies in an effort to identify cost-effective strategies. Hand and Tichatzky (1979) treated 17 OCD patients in three groups targeting OC symptoms, social interaction problems, and problem-solving ability in twice-weekly group sessions containing *in vivo* exercises, homework assignments, communication skills training, and separate support group meetings for spouses. Some decrease was observed in OCD symptoms and anxiety, but this varied considerably across groups. Two smaller case series employed 10–14 group sessions of education, goal setting, behavioral skills training, exposure, response prevention, homework logs, and cognitive restructuring (Epsie, 1986; Taylor & Sholomoskas, 1993). Benefits at the end of treatment and at follow-up were substantial and generally comparable to individual treatment trials.

Several large trials have been reported. Enright (1991) treated 24 patients (approximately six per group) for nine weekly 90-minute sessions using a similar multidimensional behavioral treatment that included assertiveness training. The author reported significant improvement in OCD symptoms and functioning at post-test and six-month follow-up, although only 17% were clinically significantly improved. In a second uncontrolled trial, Krone, Himle, and Nesse (1991) treated 36 OCD patients in seven-week groups that included instruction in self-treatment and therapist-directed ERP during treatment sessions with an optional family psychoeducational session. YBOCS scores reduced significantly to below clinical levels at three-month follow-up, and improvement occurred regardless of medication use. In two studies by Van Noppen and colleagues, 10 sessions of group ERP were used to treat a total of 90 patients with OCD. YBOCS scores again reduced significantly (an average of 5 to 10 points) and general functioning also improved (Van Noppen, Pato, Marsland, & Rasmussen, 1995; Van Noppen et al., 1996). See Table 1 for details of outcome on YBOCS scores for group ERP treatment.

In the only controlled trial of group ERP, Fals-Stewart, Marks, and Schafer (1993) compared group ERP with or without imagined exposure ($N=30$) to comparable individual treatment ($N=31$) and to an individual relaxation control treatment ($N=32$). Following 24 sessions over a 12-week period, subjects in both exposure treatment conditions improved significantly in OCD symptoms, whereas the relaxation control group changed only on anxiety. Post-test YBOCS scores fell below the clinical range. Individual treatment led to comparable but somewhat more rapid change (see Table 1). Because this study excluded patients with major depression and Axis II diagnoses, both common in OCD as noted above, a replication is needed to determine the generalizability of these findings to a more representative sample. Nonetheless, the benefits of a group modality for delivery of ERP are quite clear.

6.17.6.2.7 Family treatment for OCD

As noted earlier, researchers have commented on the adverse effects of OCD symptoms on family functioning and the often extensive family involvement in patients' OCD symptoms (Marks et al., 1975; Calvocoressie et al., 1995). Several researchers have suggested advantages for support group involvement of both patients and family members. In an early study, Marks et al. (1975) employed an open-ended monthly group for family members and patients to discuss the effect of OCD on the family and to plan coping strategies and rehearse behavioral exercises. More recently, several reports have outlined psychoeducational focuses for time-limited family support groups, including sessions on diagnosis, assessment, theories of OCD, behavioral treatment, medications, and prevention of relapse (e.g., Black & Blum, 1992; Tynes et al., 1992). Psychoeducational goals included improving self-esteem, sharing feelings and experiences, accepting patients' realistic limitations, and learning strategies for coping with OCD symptoms. These reports noted high participant satisfaction with psychoeducational groups, but provided no outcome data.

Hafner (1982) and others (e.g., Cobb, McDonald, Marks, & Stern, 1980; Hoover & Insel, 1984) described cases in which patients improved when spouses or family members participated in the behavioral treatment process. However, group trials that examined inclusion of family members in ERP have produced mixed results. Although early results by Emmelkamp and DeLange (1983) indicated that spouse assistance in exposure treatment might improve outcome, a second larger study indicated no difference in immediate or follow-up outcome, despite improvement in marital satisfaction (Emmelkamp, de Haan, & Hoogduin, 1990). However, in this trial, treatment may have been too brief (eight sessions in five weeks) to permit differences to be detected, and the lack of communication training regarding OCD symptoms (see Emmelkamp, Kloek, & Blaauw, 1992) may have reduced family-assisted treatment efficacy. These negative findings are contradicted by Mehta (1990) who reported that involving spouses and other family members in ERP for 30 patients in India led to significantly greater gains in OCD symptoms, mood state, and social and occupational functioning, compared with unassisted treatment. At follow-up, family-treated patients continued to improve, whereas individually treated patients lost some gains, suggesting that family involvement may be especially useful in forestalling relapse. An analysis of family processes affecting outcome indicated that nonanxious, consistent family members were more successful in providing support and supervision than anxious and inconsistent ones, especially those who engaged in argument and ridicule. The discrepant findings from these studies could reflect study differences in treatment length, family role, and cultural differences in the populations of Western Europe and India (see Hafner, 1992).

Thornicroft, Colson, and Marks's (1991) impatient treatment program in the UK emphasized self-treatment and teaching relatives to reduce their involvement in rituals and to encourage self-exposure in a noncritical manner. Relatives practiced these skills under the therapist's supervision on the ward. Average symptom decreases of 45% at discharge and 60% at a six-month follow-up, with clear improvement in functioning, indicated good success for this very disabled inpatient population. Similarly, Van Noppen et al. (1996) treated 19 patients in three co-therapy groups that included spouses/partners, parents, and other relatives in 10–12 two-hour sessions. YBOCS scores were reduced substantially to below clinical levels and the reductions were still significant at one-year follow-up. Improvement was also evident on disability scores. In this era of managed care, efforts to reduce costs while maintaining efficacy argue for the potential value of group and family behavioral interventions for OCD.

6.17.6.3 Cognitive Theories of OCD

A number of cognitive theories of OCD grow out of an appraisal model (Lazarus, 1966) in which appraisals of threat (primary appraisal) and appraisals of coping resources (secondary appraisal) are considered central to the development of OCD. As noted earlier, Carr (1974) observed that obsessive compulsives make abnormally high estimates of the probability of unfavorable outcomes. That is, they more often anticipate danger or negative outcomes than do nonobsessionals. Carr (1974) suggested that compulsive behaviors are intended to reduce the threat created by this erroneous judgment of risk. McFall and Wollersheim (1979) expanded on this idea and theorized that the overestimate of threat by patients with OCD is part of an inaccurate primary appraisal process (cf Lazarus, 1966) which contributes to the development of OCD. They proposed that four types of beliefs or assumptions contribute to inaccurate appraisal and result in the overestimation of negative outcomes. These include beliefs about the need for perfect competence to feel worthwhile and avoid criticism; that making mistakes or failing to meet one's ideals should result in punishment or condemnation; that one has power to prevent disastrous outcomes by magical rituals; and that certain thoughts and feelings are unacceptable, potentially catastrophic, and worthy of punishment. McFall and Wollersheim also suggested that patients with OCD are deficient in secondary appraisal of their abilities to cope with threat.

In a very similar vein, Guidano and Liotti (1983) outlined a cognitive model of OCD that emphasized two primary features: the need for perfection and for certainty to avoid criticism and risk. These theorists further suggested that three of the irrational beliefs described by Ellis (1962) are especially relevant in OCD. These are that one should be thoroughly competent, adequate, and achieving in all possible respects to consider oneself worthwhile; that one should be very concerned about potential danger and dwell on the possibility of its occurring; and that perfect solutions to all problems are available and should be sought. A similar model was also proposed by Warren and Zgourides (1991) whose rational emotive therapy model derives from Ellis's concepts. Like other appraisal models, it also emphasizes the role of irrational beliefs. They propose that unpleasant or stressful events produce intrusive thoughts. If irrational beliefs are related to these intrusive thoughts, they become important and develop into obsessions. The above theories are clearly similar with regard to the specific irrational beliefs hypothesized to be most central to OCD. As evident below, these proposals have been largely subsumed by more recent cognitive theorizing.

The best articulated and experimentally supported cognitive theory of OCD has been proposed by Salkovskis (1985, 1989) who has drawn heavily from Beck's (1976) cognitive theory of emotional disorders. In this model, Salkovskis relies on extensive research showing that intrusive cognitions are normal phenomena experienced by over 90% of the population (e.g., Freeston, Ladouceur, Thibodeau, & Gagnon, 1991; Rachman & deSilva, 1978; Salkovskis & Harrison, 1984). Thus, what distinguishes people with OCD is not the experience of intrusive thoughts, but the way in which their occurrence and content are interpreted. While most people simply are surprised by and merely ignore these intrusions, people with OCD ascribe special importance to them. According to Salkovskis, a set of underlying beliefs determines the reaction to negative intrusive experiences in people with OCD. These underlying beliefs are characterized by an exaggerated sense that one is responsible for harm to oneself or others and must act to prevent it. When the intrusive thought is interpreted in this light, the person seeks to reduce the discomfort by engaging in some form of neutralization (i.e., compulsion, suppression, or avoidance). Although the role of responsibility in OCD has been described by a number of previous theorists (Rachman & Hodgson, 1980; McFall & Wollersheim, 1979), Salkovskis refined the concept and elevated it to an explanatory level. This theory suggests that two things happen in OCD. First, patients appraise the intrusive thought as an indication that they are in some way responsible for harm or its prevention. Second, this appraisal elicits neutralizing behavior (overt or covert). If some other form of negative appraisal occurs without the appraisal of responsibility, Salkovskis suggests that neutralization will not take place and the result will be anxiety and/or depression, but not OCD. Thus, the core hypothesis/assumption of this model is that OCD symptoms are neutralizing efforts to address the appraisal of responsibility for harm.

Responsibility has been discussed already in the context of cognitive characteristics of OCD. Neutralization has been defined as "voluntarily initiated and conducted activity which is intended to have the effect of reducing the perceived level of responsibility" (Salkovskis, Richards, & Forester, 1995, p. 285), linking such efforts to responsibility. Included in neutralization are overt behaviors (washing, checking, etc.), as well as mental events, attempts to put things right, thought suppression, and reassurance seeking. Consistent with earlier anxiety-reduction models, Salkovskis et al. (1995) suggested that neutralization effectively reduces the level of perceived responsibility in the short run, but increases the probability of intrusive thoughts in the longer term.

A great deal of research has been generated by this model, much of it supporting the basic contention that responsibility is a primary feature of OCD. Experimental manipulations of responsibility (Lopatka & Rachman, 1995) and refinements in the nature and measurement of obsessional responsibility (Rhéaume, Freeston, Dugas, Letarte, & Ladouceur, 1995; Salkovskis et al., 1995) tend to support the theory. Some revisions and critiques have been proposed. Clark and Purdon (1993) propose that more emphasis should be given to dysfunctional beliefs about controlling thoughts and the costs of not doing so and to the role of depression in actually impairing patients' ability to control their thoughts. They also suggest that neutralization is not so much an essential component in the formation and maintenance of OCD, but develops only when other thought control efforts fail. O'Connor and Robillard (1995) criticize Salkovskis' theory, concluding that people with OCD do not react to an actual feared stimulus, nor to the perceived consequences, but instead to what they imagine might be there, despite a lack of sensory evidence to support the belief. This concept is similar to the thought-action fusion in that what is imagined seems a real possibility. They argue that a faulty inference process is responsible for OCD beliefs, and posit several types of inference errors. For example, rather than forming a hypothesis about an obsessional fear (the table is dirty) and testing it (feeling the table), people with OCD revise the evidence to fit the hypothesis (it must be dirty because I can imagine it dirty). Thus, OCD rituals are attempts to change the "fictional narrative" by altering reality. Further reality testing difficulties are evident in explanations for obsessional beliefs that make reference to superstitions, magical or pseudoscientific explanations, or rely on information that is irrelevant to the current situation. Further, O'Connor and Robillard propose that OCD patients make irrelevant or incidental associations between objects or events and use these to establish links in a way quite similar to sympathetic magic. Several other theories are cognitive in nature, but have been described earlier in the sections on information processing (Enright, 1996) and biological models (Pitman, 1987).

It is clear from the above review that observation of patients with OCD have led to a rich variety of theoretical ideas that involve cognitive conceptualizations of the origins and maintenance of this disorder. Although early cognitive treatments were not derived from theories that were specific to OCD symptoms, more recent studies have examined rational-emotive therapy (RET) and Beckian-derived cognitive therapy based somewhat more directly on some of the above ideas. The effects of these methods are detailed below.

6.17.6.4 Cognitive Treatments for OCD

Several writers have observed the ability of exposure-based therapies to modify thoughts and beliefs, particularly those about risk and danger, merely by requiring clients to remain in anxiety-provoking situations until their fear has subsided. Foa and Steketee (1979) suggested that exposure treatment may not actually correct cognitive deficits, but results in reclassification of some contexts as nondangerous. Whether exposure also modifies other types of cognitions common in those with OCD is an important question only partly addressed in studies by Emmelkamp and Van Oppen. These investigators noted minimal change in the Irrational Beliefs Inventory (IBI) following ERP (Emmelkamp & Beens, 1991; Emmelkamp et al., 1988; Van Oppen et al., 1995), but this measure may not adequately capture the cognitive domains of concern in OCD. The effects of ERP on cognitions requires further study.

Early studies of the effects of cognitive therapies on OCD examined self-instructional training (SIT) and rational-emotive therapy (RET), neither of which was designed especially for OCD. SIT consisted mainly of efforts to modify self-statements. When combined with ERP, SIT did not improve significantly on the outcome of ERP alone (Emmelkamp et al., 1980). Questioning whether SIT was an appropriate cognitive intervention for OCD, Emmelkamp et al (1988) went on to study the effects of RET, consisting of disputing irrational beliefs and making rational analyses of obsessional situations, compared with self-controlled ERP in 18 patients. Both treatments produced significant changes in most measures of OCD symptoms (average improvement 78%), with continued gains six months later (average improvement 94%) when several clients received additional therapy. RET demonstrated some superiority over exposure in improving depressed mood. In a second study of RET, Emmelkamp and Beens (1991) replicated their earlier findings in 21 clients who were randomly assigned to either cognitive therapy or exposure treatment, followed by the addition of exposure treatment for both groups. Significant improvement was evident in both groups, with no differences between them. RET was just as effective as exposure, and interestingly, combined treatment did not have an additive effect. Irrational beliefs (again measured by the IBI) declined somewhat more after RET, and interestingly, required longer to improve (four weeks after treatment) than OC symptoms.

Cognitive treatments using Beck's model (see Beck, Emery, & Greenberg, 1985), in which faulty beliefs and underlying assumptions are examined and challenged, have been examined in case studies of OCD patients. Examples of Beckian cognitive methods are explicated by Van Oppen and Arntz (1994) and by Freeston, Rhéaume, and Ladouceur (1996), particularly for obsessional patients without overt rituals. Kearney and Silverman (1990) reported good outcome when they alternated cognitive therapy and response prevention for a suicidal adolescent who refused exposure. When exposure therapy was ineffective for contamination fears related to skin cancer, Salkovskis and Warwick (1986) found that cognitive therapy altered unrealistic beliefs and produced positive gains, implying possible benefits for OCD patients with overvalued ideas. In a recent study of four patients with checking rituals, cognitive intervention focused on excessive responsibility proved successful without ERP (Ladouceur, Leger, & Rhéaume, 1995).

Two controlled trials have been conducted using Beck's cognitive methods. Cognitive therapy using exposure only in the context of behavioral experiments was compared to exposure alone by Van Oppen et al. (1995). These authors found both treatments equally effective after therapy and at follow-up, but a trend was evident for slightly better outcome with cognitive therapy (see Table 1). This trend can be questioned since the effects of ERP in this study were somewhat lower than observed in some other centers. A second study by Ladouceur, Freeston, Gagnon, Thibodeau, and Dumont (1995) treated 29 ruminators with combined exposure and cognitive therapy in a controlled waiting-list study. The combined treatment produced an 84% success rate and therapeutic gains were maintained at one-year follow-up.

From the above reports, it is evident that treatments designed to correct cognitive distortions common in OCD clients enhance immediate outcome with or without ERP and may also reduce relapse. However, some preliminary research establishing which cognitions are important in the development or maintenance of OCD symptoms, and how to assess these, has not yet been completed. Only with such information can researchers begin to determine whether desirable cognitive changes are best achieved via cognitive treatments or by other (e.g., behavioral, biochemical) methods. In the late 1990s, given the recency of study of cognition and cognitive therapy for OCD, these methods are not routinely included in standard behavioral treatment programs. Informally, however, many clinicians engage in dialogue with clients regarding their beliefs and assumptions as these surface during exposure sessions and interfere with reduction of anxiety or discomfort.

6.17.6.5 Biological Models of OCD

The discovery of effective pharmacological agents for treating OCD produced a surge of interest in biological explanations for the disorder. With the recent development of sophisticated instrumentation, methods of testing and refining hypotheses about neural substrates have produced dramatic advances in our knowledge about the biology of OCD. Current biological models can roughly be organized into two types: neuropharmacological and anatomical. The neuropharmacological explanations involve a disregulation of the serotonergic transmitter system. The anatomical explanations involve the basal ganglia, orbiotfrontal cortex, and their connecting loops. These models are not mutually exclusive.

6.17.6.5.1 The role of serotonin

The most consistent neuropharmacological evidence comes from the results of the administration of serotonin reuptake inhibitors (SRIs) as a treatment for OCD (Barr, Goodman, & Price, 1993). A plethora of evidence now indicates that the SRIs are especially effective in reducing symptoms of OCD (see Section 6.17.6.6). These findings suggest that the serotonergic system may be particularly important in the biology of OCD. Unfortunately, drug response data are not the best source of evidence for testing underlying neurochemical processes.

More direct evidence for serotonergic involvement require studies of peripheral markers of serotonin (i.e., concentrations of known metabolites of serotonin in the blood or cerebrospinal fluid) or pharmacological challenges (i.e., administering a serotonin agonist which provokes a serotonergic response in people whose serotonergic system is dysregulated). Unfortunately, studies of blood platelet measures of serotonin and cerebrospinal fluid concentrations of serotonin metabolites (5-hydroxyindoleacetic acid: 5-HIAA) have been inconsistent in establishing the role of serotonin function in OCD (Barr et al., 1993; Rauch & Jenike, 1993). It is possible that peripheral markers of serotonin in a resting state do not show functional differences between OCD and normal subjects because the body may compensate for serotonin dysregulation (Barr et al.).

The results of pharmacologic challenge studies have produced findings opposite to what would be expected based on the evidence from drug treatment studies. The effectiveness of SRIs suggest OCD patients suffer from a functional deficit in serotonin (Yaryura-Tobias & Bhagavan, 1977). However, administration of serotonin agonists have produced exacerbated OCD symptoms, suggesting that OCD sufferers have a heightened sensitivity to serotonergic stimulation (Tallis, 1995). Strengthening this finding is the reversal of this effect by administration of serotonin receptor antagonists (Benkelfat et al., 1990). Challenge study findings have not been entirely consistent, however. In reviewing this evidence, Barr et al. (1993) conclude that dysregulation of the serotonergic system is probable, but the nature of the dysregulation is unclear. While neuroendocrine responses to challenge suggest hyposensitivity, behavioral findings suggest a hypersensitivity. In light of these inconsistencies, a number of investigators suggest a more complex model of OCD taking into account multiple transmitter systems (Leckman et al., 1995; Rauch & Jenike, 1993).

6.17.6.5.2 Neuroanatomy of OCD

Anatomical models of OCD have focused on selected parts of the brain, specifically the basal ganglia, the frontal cortex, and the limbic structures connecting them. The basal ganglia are a subcortical group of nuclei involved in the regulation of movement, as well as cognitive functioning (Crutcher, 1985). Three structures in the basal ganglia make up the corpus striatum: the caudate nucleus, putamen, and globus pallidus. It is the structure and activity of the corpus striatum which has been most closely associated with OCD. Computerized tomography (CT) studies have found caudate volume to be smaller in OCD subjects than in controls (Luxenburg et al., 1988). Positron emissions tomography (PET) scan studies have found increased metabolic activity in the caudate nucleus of OCD patients during a resting state (Baxter et al., 1987, 1988). Other studies have found increased metabolic activity in the striatum during exposure among OCD cleaners (McGuire, Bench, Marks, Frackowiak, & Dolan, 1994; Zohar, Fux, Taub, & Lusel, 1989), but reduced metabolic activity among compulsive checkers (Cottraux et al., 1996). Cottraux et al. (1996) suggest that the latter converse finding may be due to the ability of compulsive checkers to engage in covert neutralization during the PET scan procedure.

In reviewing the evidence on basal ganglia involvement in OCD, Rauch and Jenike (1993) conclude that there is compelling evidence for a striatal abnormality among OCD patients, but that it is not clear whether this abnormality is primary or secondary. These studies have led to speculation about the role of basal ganglia dysfunction in the development of OCD. Wise and Rapoport (1989) have postulated that OCD is a basal ganglia disorder involving the dysfunctional release of normally inhibited "fixed-action patterns" (innate species-specific responses). In this model it is assumed that the basal ganglia stores motor programs for action which are innate, and that it forms a gating mechanism for their release. The basal ganglia detects stimuli which activate fixed-action patterns, and allows the release of these behaviors which take the form of grooming and safety rituals.

A variety of studies suggest that frontal lobe activity in conjunction with the basal ganglia are implicated in OCD. Neuropsychological assessments (see Tallis, 1995) and EEG studies are suggestive of frontal lobe deficits (Rauch & Jenike, 1993). PET studies have also suggested some type of frontal-striatal abnormality. PET studies and SPECT (single-photon-emission computed tomography) studies have consistently shown increased metabolic activity in the frontal cortex of OCD patients compared to controls (Baxter et al., 1990; Cottraux et al., 1996; Rauch & Jenike, 1993). More recent studies have shown increased metabolic activity to provocative stimulation among OCD patients (Cottraux et al., 1996; Rauch et al., 1994) as well as normal controls (Cottraux et al., 1996). Other PET studies have found that elevated metabolic activity is no longer present following successful treatment with medication or behavior therapy (Baxter et al., 1987, 1992). Evidence of hypermetabolic activity in the orbitofrontal gyri and the basal ganglia has led to theorizing that a fronto-striatal dysfunction is at the core of OCD. Insel (1992) proposed that these regions make up a cortical-striatal-thalamic-cortical circuit that is hyperactive. In this circuit the caudate nucleus sends inhibitory signals to the globus pallidus which then fails to inhibit the thalamus from sending signals to the cortex. The cortex thus receives signals that it would not receive if the circuit were operating normally. Further inhibition by the caudate nucleus prevents the circuit from being interrupted, and therefore the messages continue to reverberate.

Baxter et al. (1990, 1992) have proposed a slightly different way in which this circuit may be dysfunctional. The hyperactivity may result from faulty screening of sensory information. The gating and screening activities of the striatum may not work properly and thereby fail to inhibit impulses/thoughts which "leak" into consciousness and are experienced as obsessions. Compulsions are fixed-action patterns that occur automatically in response to this material and require effortful and conscious suppression and/or neutralization. This effort produces the hyperactivity in the basal ganglia and frontal lobes observed in OCD patients. Other models have postulated a problem with the "comparator mechanism" in the limbic system (Gray, 1984) or in the basal ganglia (Pitman, 1989) which matches sensory information with what is anticipated. When a mismatch occurs, general arousal and corrective procedures are undertaken. However, a defective comparator mechanism might result in faulty evaluation of sensory input (e.g., my hands feel dirty when they are not), and ineffective corrective action (washing my hands to remove dirt that is not there). Because of a faulty comparator, the dirt can only be felt and not removed.

While evidence is strong for some form of frontal-striatal circuit involvement as a neurological substrate of OCD, the etiological significance of this circuit is unclear. It may simply be the biological expression of the disorder and not the cause of it. There is some evidence that hyperactivity in the frontal lobes can be produced in normal subjects by processing obsessional material (Cottraux et al., 1996). Nonetheless, the substantial evidence for biological substrates associated with OCD will undoubtedly foster considerable further research to clarify the mechanisms and roles of the various biochemical substances and neuroanatomical structures.

6.17.6.5.3 *Genetics*

The findings from twin and family studies have suggested some degree of genetic influence in OCD (for reviews see Kolada et al., 1994; Pauls, 1990, 1992; Rasmussen, 1993), but these studies have not always been consistent or without problems. When diagnosis of OCD is used to define concordance, the evidence for genetic transmission is weak or inconsistent (Kolada et al., 1994). However, when subclinical OCD symptoms are used to establish concordance, the evidence is strong for a genetic factor in OCD (Black, Noyes, Goldstein, & Blum, 1992; Carey & Gottesman, 1981). The evidence of concordance for other disorders, especially anxiety disorders, has led some to conclude that what is transmitted in families with OCD is a diathesis for anxiety disorders rather than specifically for OCD (Black et al., 1992). Recent interest has been generated by the hypothesis that at least a subtype of OCD and Tourette's syndrome (TS) are different phenotypic expressions of a common underlying genotype (Pauls, 1990, 1992). As noted earlier, OCD occurs more often in TS patients and their family members, and TS occurs more often in OCD patients and their family members (see Pauls, 1990). The evidence has led some to suggest that these disorders share a common genetic underpinning (Leckman & Chittenden, 1990; Pauls, 1990).

6.17.6.6 Biological Treatments for OCD: Medications and Psychosurgery

6.17.6.6.1 *Medications*

Nearly three decades have passed since the late 1960s when the first reports of the potential efficacy of clomipramine (Anafranil) in the treatment of OCD (Stein, Spadaccini, & Hollander, 1995). Since that time a number of more selective SRIs have been developed and investigated as treatments for OCD, including fluvoxamine (Luvox), fluoxetine (Prozac), and sertraline (Zoloft). A substantial number of clinical and placebo-controlled trials have now been conducted with these medications. Qualitative reviews of the treatment outcome literature (Jenike, 1990; Rasmussen, Eisen, & Pato, 1993; Steketee, 1993), as well as quantitative (meta-analytic) studies (Greist, Jefferson, Kobak, Katzelnick, & Serlin, 1995; Piccinelli, Pini, Bellantuono, & Wilkinson, 1995; Stein et al., 1995), provide a useful overview of the effectiveness of the serotonin transport inhibitors. Based on double-blind, placebo-controlled studies, these reviews conclude that all of these SRIs are effective in the treatment of OCD with at least a moderate improvement occurring in from 55–70% of previously untreated patients (Rasmussen, Eisen, & Pato, 1993; Steketee, 1993). The average effect sizes from meta-analytic studies range as high as 1.48–1.64 (Greist et al., 1995; Stein et al., 1995). Table 1 presents findings for medication studies using the YBOCS as an outcome measure.

Although early studies with clomipramine suggested that its antidepressant effect was responsible for at least some benefit in OCD symptoms (Marks, Stern, Mawson, Cobb, &

McDonald, 1980), more recent studies indicate that SRIs work for OCD patients whether or not they are depressed. Comparisons of SRIs with other non-SRI drugs have all favored the SRIs in the treatment of OCD (Jenike, 1993). A newer SRI, paroxetine (Paxil) has also shown promise in recent studies (Kaye & Dancu, 1994).

Very few studies directly compare the effectiveness of SRIs to each other. Comparisons of the efficacy of CMI versus fluoxetine have failed to find differences (Freeman, Trimble, Deakin, Stokes, & Ashford, 1994; Pigott et al., 1990). However, a meta-analytic comparison found CMI effect sizes (1.53 to 1.84) to be larger than those for fluoxetine (1.34) (Jenike, Baer, & Greist, 1990). Other meta-analytic studies have tended to show a similar preference for CMI (Greist et al, 1995; Stein et al., 1995), although at least one such study has been equivocal on this issue (Piccinelli et al., 1995). (See also Table 1.) Despite these indications that CMI is more effective than the other SRIs, more large-scale direct comparisons of treatment efficacy are needed before drawing definitive conclusions regarding the differential effectiveness of these drugs. There are several reports which suggest the method of administration of SRIs may influence their efficacy. In several clinical series, intravenously administered CMI worked significantly faster than oral methods (Sallee, Pollock, Perel, Ryan, & Stiller, 1989; Koran, Faravelli, & Pallanti, 1994) and, of particular importance, IV administration was effective for treatment of refractory patients (Fallon et al., 1992).

While the effectiveness of SRIs in the treatment of OCD has been established, it should be noted that the response to these medications is not usually a complete cessation of symptoms. In fact, Jenike (1990) estimates that patients treated with SRIs show only a 30–60% reduction in their symptoms, and 30% or more show no improvement at all (Rasmussen et al., 1993). Furthermore, most patients remain "chronically symptomatic." There is no question that the medications improve the symptom picture for patients with OCD, but the SRIs do not represent an ideal solution in the treatment of OCD.

Although the tolerableness of the side effects of SRIs is generally better than that of tricyclic antidepressants (Montgomery & Kasper, 1995), it is still of some concern in OCD. Major side effects include sedation, sexual dysfunction, and weight changes (Rasmussen et al., 1993). Other side effects vary somewhat as a function of the specific medication. Rasmussen et al. conclude that CMI has the most problematic side effects profile. These side effects may compromise patient compliance or necessitate dosage reductions which may make the treatment less effective (Clomipramine Collaborative Study Group, 1991). For CMI the side effects are mainly anticholinergic. There is a slight chance of seizures, especially at higher dosages (DeVeaugh-Geiss, Landau, & Katz, 1989) and partial or total anorgasmia is common (Monteiro, Noshirvani, Marks, & Lelliott, 1987). Although many patients may be willing to tolerate the anorgasmia for the symptom relief provided by CMI, it is a major cause of treatment dropout (Rasmussen et al.). For fluoxetine, up to 50% of patients reported side effects including fatigue, nausea, insomnia, tremor, and sexual dysfunction (Jenike, 1990). Similar side effects have been reported for fluvoxamine (Jenike, 1990), although in direct comparison, CMI had more anticholinergic side effects and more sexual dysfunction while fluvoxamine-treated patients reported more headaches and insomnia (Freeman, Trimble, Deakin, Stokes, & Ashford, 1994). In a comparison of the side effects of CMI and fluoxetine, Jenike et al. (1991) found that only 3% of patients had no side effects from CMI while 43% had no side effects on fluoxetine.

Other problems associated with use of medications include dropout, relapse on or off medication, and inadequate response. Dropout or noncompliance rates for SRIs have not been well studied. Recent reports range from 10 (Tollefson, et al. 1994) to 26% (Freeman et al., 1994). Most studies provide insufficient information to determine dropout rates. In a comparison of four large clinical trials, Greist et al. (1995) reported significantly fewer dropouts for CMI (12.5%) than for other SRIs (23–27%). Little information exists on relapse rates following cessation of SRI treatment. Pato, Zohar-Kadouch, Zohar, and Murphy (1988) found a nearly 90% relapse rate within seven weeks of discontinuation of CMI. Furthermore, the length of treatment was not related to relapse. Likewise Leonard et al. (1991) found an 89% relapse rate when desipramine was substituted for CMI. In two reports on relapse during continued medication treatment, Leonard et al. found an 18% relapse rate two months after successful CMI treatment, and Fontaine and Chouinard (1989) found a 23% relapse rate after one year on fluoxetine.

As noted earlier, a substantial number of OCD patients do not respond or respond marginally to SRI treatment. Although it is not clear who will not respond favorably to SRIs, there are several suggestions in the literature. In Ackerman, Greenland, Bystritsky, Morgensterns, and Katz's (1994) review of predictors from a multicenter clinical trial of over 500 patients, the only predictor of treatment response was age of onset.

Patients who develop OCD later in life showed a significantly better response to SRIs, a finding contrary to that for behavioral treatment where early onset is associated with better outcome (Foa et al., 1983). Additionally, patients with comorbid schizotypal personality disorder do not appear to respond well to SRI treatment (Jenike, 1990). Augmenting SRI treatment for patients who show an inadequate response has been the subject of some research. Evidence suggests that patients with comorbid tic disorders or schizotypal personality who are treatment resistant to SRIs may respond to the addition of neuroleptics (e.g., Goodman, McDougle, Barr, Aranson, & Price, 1993; McDougle, Goodman, Leckman, & Price, 1993).

6.17.6.6.2 Psychosurgery

For patients who do not respond to multiple medication trials or behavior therapy, psychosurgery may be an option. The development of stereotactic techniques appears to have resulted in more precise lesion placement, increasing the safety of psychosurgery techniques and reducing their side effects. Four types of psychosurgery are currently used for treatment of OCD: cingulotomy, capsulotomy, limbic leucotomy, and subcaudate tractotomy (Mindus & Jenike, 1992). No controlled trials of the effectiveness of psychosurgery have been conducted on the uncontrolled studies; improvement rates between 25 and 100% have been reported (Chiocca & Martuza, 1990; Jenike et al., 1991; Baer et al., 1995). These improvement rates should be viewed with caution since most are based on early studies before current behavioral and medication treatments were adequately developed. Whether such high rates of improvement will be observed among patients who have failed to respond to multiple medication trials and behavior therapy remains to be seen. At least one recent study (Baer et al.) reported a 45% improvement rate (substantially improved plus partial treatment responders) following cingulotomy for patients who had adequate but unsuccessful presurgery treatments. Following a thorough review of the available evidence on effectiveness and side effects, Chiocca and Martuza (1990) recommend cingulotomy as the first procedure, based primarily on the low rate of complications following this surgery.

6.17.6.7 Combined Interventions for Treatment of OCD

We have already discussed the effects of combined cognitive and behavioral treatments for OCD: combinations did not usually improve upon either treatment administered alone. Likewise, behavioral treatments have also been combined with pharmacological ones, although to date surprisingly few studies have undertaken controlled comparisons of these combinations. Two studies by Marks and colleagues compared clomipramine to placebo, and behavioral treatment to relaxation (Marks et al., 1980) and to antiexposure instructions (Marks et al., 1988). In the first study, CMI improved mood and OCD symptoms and behavior therapy led to additional improvement on most OCD symptoms, but not on mood. Combined clomipramine plus exposure therapy was only slightly better than drug alone at 10 weeks. After two years (Mawson, Marks, & Ramm, 1982) and six years (O'Sullivan, Noshirvani, Marks, Monteiro, & Lelliott, 1991), improvement in OCD symptoms generally continued. At the latter follow-up, most patients (61%) reported taking medication, but only 25% had continued on clomipramine. After six years, the original CMI-treated group improved more than the placebo group on only one of 16 measures. In Marks et al.'s second study (1988), CMI initially enhanced the effect of exposure but this disappeared with continued exposure treatment and was not evident at follow-up. In both Marks et al. studies (1980, 1988) greater average improvement occurred with exposure compared to CMI, and in the later study 75–80% of patients improved with ERP compared to 22–33% for CMI. Combined treatment led to more subjects who were "much improved" after one year (73% vs. 50% for exposure alone), but not to more average improvement.

A third study compared fluvoxamine to this medication plus exposure and to placebo plus exposure (Cottraux et al., 1989). Behavior therapy had a poorer showing compared to other studies (see above). All three groups improved, with only a slight advantage for combined drug and behavioral treatment at six months. In contrast to the studies by Marks et al., fluvoxamine led to more average improvement than exposure and produced more successes (54% vs. 40%) at post-test (Cottraux et al.). However, one year later, mean improvement was nearly equivalent across treatments and slightly more exposure patients were improved (50% vs. 45%). The combination treatment showed some potentiating effect at six months, but this was minimal after a year. With only three studies conducting a head-to-head comparison of ERP and SRI or SSRI medications, there is clearly inadequate evidence to judge whether combined treatment offers advantages or whether either treatment alone is the best choice for particular patient groups. Recent research by Foa, Liebowitz and colleagues (Foa et al., 1993) suggests that ERP is more effective than clomipramine and more effective than the combination. However, conclusions are premature since this study has not yet been completed and study inclusion criteria were stringent, reducing generalizability of findings for clinical OCD patients.

Meta-analysis of ERP and SRI-medication effects provide some information pertinent to this issue. In 1987, Christensen and colleagues concluded that behavioral and pharmacological interventions were equivalent in efficacy, though they acknowledged that their methodology may have overestimated medication effects (Christensen, Hadzi-Pavlovic, Andrews, & Mattick, 1987). A more recent meta-analysis by van Balkom et al. (1994) concluded that both ERP alone and ERP plus medications was more effective than SRIs on self-rated measures. However, they found no differences when assessor-rated measures were used. A recent review of findings concurred with van Balkom and others that the lack of equivalent measurement instruments makes the task of comparing these treatments and their combinations very difficult and equivocal at best (Stanley & Turner, 1995). With the general adoption of the Yale–Brown Obsessive Compulsive Scale (YBOCS, Goodman et al., 1989), it appears that this problem is being addressed. Table 1 includes several pharmacological, behavioral, and cognitive studies that employed the YBOCS to assess outcome. A visual comparison of findings shows substantial reductions using medications, with post-test scores generally ranging from 14 to 19. Unfortunately, few studies included follow-up results, but these were positive in two studies so long as medications were continued. Post-test scores for ERP treatments (and the single cognitive therapy) ranged from 9 to 17 with consistently stable gains at follow-up. These studies show a range of outcomes, with somewhat more average benefits for the behavioral methods.

6.17.7 FUTURE DIRECTIONS

In the above review, we have discussed a variety of areas of clinical research regarding the psychopathology and treatment of OCD. Although much is now understood about this disorder, there remain significant areas in need of further investigation. For example, the level of insight into obsessions varies across subclinical and clinical populations, and even within subjects depending on the mood state or context, but it is not clear whether some treatments (e.g., cognitive therapies) can change insight or even whether insight influences treatment response. The similarities of some diagnoses to OCD (e.g., bulimia, hypochondriasis) argue for possible underlying pathology, but to date research has only hinted at some shared characteristics (e.g., biological traits, treatment response). In view of the increasingly common use of the term "OC Spectrum" conditions that include impulsive disorders (e.g., gambling, trichotillomania), determination of the exact relationship, if any, of these conditions to OCD is needed before the field becomes attached to conceptual views and treatment tactics that may be inaccurate.

Some findings suggest that there may be subtypes of OCD. For example, one subgroup appears to be early-onset males with tics and/or schizotypal traits and poor insight, who are refractory to common treatment packages such as SRIs and ERP. It is important to determine whether patients with particular combinations of OCD characteristics or comorbidity benefit more from specialized combinations of treatments (e.g., addition of neuroleptics, social skills training, or change in living situation). Correspondingly, in view of cultural similarities and differences in OCD symptom pictures, should modifications be made to psychosocial treatments to accommodate cultural context, and if so how? For example, Williams, Chambless, and Steketee (1996) have suggested some modifications to ERP for African-American patients who showed specialized treatment response patterns. Along the same vein, before we proceed too far with inclusion of significant others in the treatment process, it is important to understand how these individuals influence patients' symptoms before and during therapy. It may be that for some patients, including family members in therapy is detrimental rather than helpful, whereas for others, family involvement may be essential to recovery.

Two areas engendering intensive research in recent years are, first, biological underpinnings of OCD and corresponding pharmacological treatments; and second, cognitive traits and theoretical models, and cognitive psychotherapy. With the availability of more precise capabilities to physically examine chemical and structural mechanisms, researchers have intensified their search for essential factors involved in the pathogenesis of this disorder. Efforts to identify effective biological treatments have also progressed rapidly, although these two areas of research are not always closely connected. Baxter and colleagues' (1992) case reports of neurochemical changes following effective drug and behavioral therapy are extremely interesting but require replications in controlled trials from other centers. Likewise, research on cognitive features and information processing has burgeoned recently with studies ongoing across various centers.

In the search for both biological and cognitive substrates and treatments, there is some tendency to test treatments for which theoretical models and assessment strategies are not fully conceptualized. As a result, treatment components are sometimes underdeveloped. This cart-before-the-horse phenomenon is understandable given the severity and debilitating costs associated with OCD. Nonetheless, thoughtful progression from conceptual models to treatment strategies is needed to ensure that newly developed interventions will work. In the current climate of health care cost containment, research on cost-effective treatments for OCD has, not surprisingly, focused on medication regimens and group interventions. However, it is important to bear in mind that cost-effectiveness may not mean briefer interventions, particularly for long-standing or complex symptom pictures. Further research in this area will certainly be needed in the immediate future.

6.18.1 INTRODUCTION

Panic attacks are characterized by sudden and apparently inexplicable increases in anxiety accompanied by a range of intense bodily sensations. Over the last two decades, clinical problems characterized by recurrent panic attacks have become a major focus of biological and psychological research into anxiety. Probably the main reason for this upsurge in interest in panic was the nearly simultaneous development of effective psychological and biological treatments for a range of anxiety disorders, coupled with the growing awareness of the relevance of panic attacks to treatment outcome (Rachman, 1990).

The strong association between panic attacks and avoidance behavior, particularly in agoraphobia, has led many writers to the conclusion that panic attacks are the principal *cause* of agoraphobia (Barlow, 1988; Klein, Ross, & Cohen, 1987; Rachman, 1990; Thyer, 1986; Thyer & Himle, 1985). Even when not accompanied by agoraphobic avoidance, panic attacks are associated with considerable distress as well as social and occupational handicap (i.e., in Panic Disorder). The importance of the phenomenon of panic goes beyond these conditions, however; it has been demonstrated that panic attacks are prevalent in all other anxiety disorders (Barlow et al., 1985). A number of studies have also shown that panic also occurs relatively frequently in nonclinical subjects (Margraf & Ehlers, 1988; Norton, Dorward, & Cox, 1986; Norton, Harrison, Hauch, & Rhodes, 1985), and that subjects with infrequent (nonclinical) panic share many of the characteristics of patients diagnosed as suffering from Panic Disorders. Such observations have led to the suggestion that infrequent panic represents the nonclinical end of an agoraphobic continuum (Rachman, 1990), challenging earlier suggestions that agoraphobia is discontinuous from normal fear (Arrindell, 1980; Roth, 1959).

Current psychological thinking tends to assume that panic and agoraphobic avoidance may have a common basis in psychological factors which are normally distributed in the general population, and that anxious patients are people who are especially vulnerable to the development of specific anxiety disorders as a result of being at the extreme end of such a continuum or several continua. The basis of the putative underlying dimensions seems likely to be cognitive (McNally, 1990, 1994; Rachman, 1990; the psychological basis of dimensional approaches to panic is discussed in greater detail in Salkovskis, 1988a).

Although panic attacks have been recognised since the nineteenth century (albeit in various forms and with a range of descriptive labels), the importance of panic attacks was only formally recognised on the introduction of the third edition of the *Diagnostic and statistical manual of mental disorders* (*DSM-III*) of the American Psychiatric Association (American Psychiatric Association, 1980). In *DSM-III*, the presence of relatively frequent panic attacks, some of which were spontaneous (i.e., uncued and unexpected) was defined as pathognomonic of two conditions in the anxiety disorders grouping; Panic Disorder and Agoraphobia with Panic.

The *DSM* description of panic (currently in the form of *DSM-IV*) has become the standard way of operationally defining panic attacks and Panic Disorder, with and without agoraphobia. Table 1 gives the *DSM-IV* criteria for panic. There are a number of shortcomings of this definition. Perhaps the most important of these concerns the definition of panic frequency; it is possible to obtain a diagnosis of Panic Disorder as a result of a single panic attack followed by a period of at least one month's apprehension of having another. This definition could have the result that some control subjects in investigations into panic may experience more frequent panic attacks than some patients in the Panic Disorder groups. The obvious solution (and the one employed by many research groups) is to supplement *DSM-IV* definitions of Panic Disorder with the requirement that panic subjects should be currently experiencing panic attacks at a predefined frequency.

As is clear from the criteria in Table 1 that the strong association between panic attacks and avoidance behavior, particularly in agoraphobia, has led many writers to the conclusion that panic attacks are the principal cause of agoraphobia (Barlow, 1988; Klein et al., 1987; Rachman, 1990; Thyer, 1986; Thyer & Himle, 1985). Even when the diagnosis is of agoraphobia without a history of panic attacks this depends on the "presence of agoraphobia related to fear of developing panic-like symptoms (e.g., dizziness or diarrhea)." Although it is recognized here that panic and panic-like symptoms are important for (and often central to) the experience of a substantial proportion of agoraphobics, the attribution of all agoraphobia to panic and panic-related symptoms may be premature (Salkovskis & Hackmann, 1997). Nevertheless, the last two decades has seen the concept of agoraphobia fade and become subsidiary to panic.

Table 1 Criteria for panic disorder with and without agoraphobia.

For a diagnosis of Panic Disorder, at least two unexpected attacks must occur, characterized by at least four of the symptoms listed below

Also requires:

Recurrent and unexpected panic attacks and at least one of the attacks is followed by at least one month of persistent concern about having additional attacks, or worry about the implications of the attack or its consequences (such as losing control or having a heart attack) or a significant change in behavior related to the attacks

Panic must also be unexpected, i.e., did not occur immediately before or on exposure to a situation that almost always caused anxiety, or produced by another disorder (social phobia, obsessive-compulsive disorder, post-traumatic stress disorder, or separation anxiety disorder)

Symptoms (criteria specify an increase in at least four in at least one attack)

Physical
- Shortness of breath
- Choking
- Palpitations or tachycardia
- Chest pain or discomfort
- Sweating
- Nausea or abdominal distress
- numbness or tingling sensations
- depersonalization or derealization
- flushes or chills
- trembling or shaking
- feeling dizzy, lightheaded, unsteady, faint

Mental
- Fear of dying
- fear of losing control or going crazy

Other characteristics

At least four or more symptoms developed abruptly and reached a peak within 10 minutes of the beginning of the first symptom noticed

Can be associated with avoidance behavior (especially agoraphobia and anticipatory anxiety)

Onset can be associated with physical disorder or factors; diagnosis depends on the persistence beyond the cessation of precipitating organic factors (e.g., Hyperthyroidism, caffeine intoxication, etc.)

Painc Disorder with Agoraphobia: as above, but in addition

Anxiety about being in places or situations from which escape might be difficult (or embarassing) or in which help may not be available in the event of having an unexpected or situationally predisposed panic attack or panic-like symptoms. Agoraphobic fears typically involve characteristic clusters of situations that include being outside the home alone; being in a crowd or standing in a line; being on a bridge; and traveling in a bus or train. The situations are avoided or endured with marked distress or with anziety about having a panic attack or panic-like symptoms, or require the presence of a companion

6.18.2 DEVELOPMENT OF THE PANIC CONCEPT

6.18.2.1 Lay and Psychiatric Conceptualizations

The term "panic" is said to be derived from the Greek *to panikon deima*, which was a description of the effects on lone travelers of sudden noises made by the God Pan (Baker, 1989). There are a number of literary allusions to panic from Classical Greek times onwards. Most descriptions seem to concern identifiable responses to extraneous stimuli and situations, such as the effects of apparent reverses during battle or of sudden noises. More "scientific" descriptions of anxiety began to appear during the nineteenth century (notably those of Charles Darwin and William James), although these do not appear to have been related to panic as such. Modern writers have suggested that early descriptions of a range of syndromes (such as neurasthenia, effort syndrome, etc.) may have been descriptions of Panic Disorder (Skerrit, 1983). While this is possible, such attempts to pinpoint early descriptions of Panic Disorder tend to be overinclusive. For example, careful examination of early and late descriptions of "Neurasthenia" (e.g. Beard, 1869; Cohen & White, 1951) indicate a quite different pattern of symptoms, probably including characteristic subgroups of anxious and depressed patients whose main complaint was weakness on exercise, often more closely resembling modern accounts of Chronic Fatigue Syndrome. That there may have been overlaps with modern diagnoses is not impossible, but the presence of these type of accounts cannot be taken as evidence of the ubiquity of the diagnosis of Panic Disorder.

More relevant are explicitly psychiatric accounts of anxiety problems such as that of Westphal (1872), who identified a specific constellation of symptoms which were characteristic of what we now recognize as panic associated with Agoraphobia. It fell to Freud (1894, 1895) to specifically identify episodic and "anxiety attacks" (*Angstanfaelle*) which were not triggered by specific situations and tended to be unexpected; he described such episodes as being important symptoms in defining "anxiety neurosis." Anxiety neurosis was said to be characterized by acute dread and fear of death, night terrors, phobias, vertigo, parasthesias, hypervigilance, excessive arousal, and anxious expectation (Lewis, 1967). Freud defined anxiety attacks, which were often preceded by periods of generally heightened anxiety, as suddenly breaking through and being accompanied by a range of physical sensations similar to those recognized today by the *DSM-III-R* definition. Anxiety attacks continued to be intermittently described by psychiatric writers such as Diethelm and Fenichel, but invariably as a symptom of underlying anxiety (Baker, 1989) rather than as defining features.

The 1960s were marked by an increased prominence afforded to panic attacks, with the importance of the concept of panic being championed by Klein (1964), who described what he believed to be the specific responsiveness of anxiety characterized by panic to imipramine but not to phenothiazines (this work is often wrongly described as being a comparison of imipramine compared with benzodiazepines, based on the use of the term "tranquilizers"). Subsequently, this "pharmacological dissection" was extended to show that benzodiazepines benefited those with generalized and phobic anticipatory anxiety but not those with panic (Zitrin, 1983; Zitrin, Woerner, & Klein, 1981). Others enthusiastically took up the view that panic attacks were a distinct marker of a different, possibly endogenous type of anxiety (e.g., Snaith 1968). At about the same time, Pitts and McClure (1967) demonstrated that anxiety attacks could be precipitated by intravenous infusions of the alkaline substance, sodium lactate. Later work showed that this effect was specific to patients with Panic Disorder as opposed to other anxiety disorders (Klein, 1981), and that prior administration of imipramine blocked the response to lactate (Rifkin, Klein, Dillon, & Levitt, 1981). Taken together, this data was believed to indicate that panic attacks were the core manifestation of a specific biological dysfunction and that psychological aspects such as agoraphobic avoidance were entirely secondary (Klein, 1980; Klein et al., 1987; Sheehan, 1982). This view on the primacy of panic attacks was in sharp contrast to Freudian conceptualizations current in the 1970s, in which panic was regarded as a secondary phenomenon, with free-floating anxiety (unfocused anxiety arising from subconscious conflicts) being the supposed origin of panic.

An important corollary of Klein's biological hypothesis was that panic anxiety unlike anticipatory or phobic anxiety was, by virtue of its endogenous nature, *unaffected by psychological influences*. This assertion extended to statements concerning the ineffectiveness of psychological treatments, including exposure (Zitrin, Klein, & Woerner, 1980). Klein's view was the basis for the definition adopted by *DSM-III* (American Psychiatric Association, 1980) and its modification, *DSM-III-R* (American Psychiatric Association, 1987). Not surprisingly, psychological theorists and practitioners began to challenge the primacy of endogenous and biological factors in panic and its treatment.

6.18.2.2 The Development of Psychological Conceptualizations of Panic

With the early interest in panic arising from biological findings, those involved in psychological conceptualization were slow to acknowledge the diagnostic importance of panic, and some still dispute the value of the label (Marks, 1987a, 1987b). Perhaps the most influential early *psychological* account of the nature of panic attacks was that of Lader and Mathews (1968,1970). Drawing on their previous theorizing concerning the tendency of arousal to inhibit habituation, and, in more extreme instances, to result in sensitization, they postulated that panic attacks were the consequence of an inhibitory function which occurred if the arousal/sensitization process proceeded too far. Thus, the function of panic attacks was said to be to dampen down physiological responses in an "over excited" system. Although this hypothesis did not receive support from subsequent research, it was influential because it introduced the idea of the interaction between psychological and physiological factors in panic. Aspects of this view can be found in Barlow's hypothesis concerning the role of background stress (Barlow, 1988).

The later emphasis on cognitive conceptualizations resulted in a number of psychological hypotheses intended to account for panic attacks occurring in association with agoraphobia, based on the notion that panic was the result of "fear of fear." The most important advocates of this position are Goldstein and Chambless (1978), Chambless and Goldstein (1980), Chambless and Gracely (1989), and Weekes (1977). The fear of fear hypothesis is based on the idea of an ascending spiral in which the patient who enters or anticipates confronting an anxiety provoking situation becomes afraid of the possibility of experiencing fear (e.g., Foa, Steketee, & Young, 1984). Clark (1988) has pointed out that earlier versions of the fear of fear hypothesis tend to over predict the occurrence of the panic spiral; in panic prone subjects, any occurrence of anxiety should result in panic. Later versions of this hypothesis propose that fear of the consequences of anxiety and panic may also play an important part (e.g., Chambless & Gracely, 1989). With later modifications, the fear of fear view closely resembles the cognitive hypothesis of panic discussed below. These modifications concern reconceptualizing fear of fear to fear of the *consequences* of fear (e.g., patients may fear that anxiety will put a dangerous strain on their heart).

6.18.3 PREVALENCE OF PANIC

The importance of the phenomenon of panic is highlighted by epidemiological findings that not only is Panic Disorder *per se* very common, but also that a considerable proportion of nonclinical subjects surveyed experience panic attacks, and that panic attacks frequently coexist with a range of other disorders, especially (but not exclusively) other anxiety disorders. In considering the prevalence of panic, it is important to distinguish between the prevalence of occasional *panic attacks* (often described as nonclinical panic when noted in the general population) as opposed to *Panic Disorder*, which is an operationally defined diagnosis in *DSM-IV*; see below). A number of large-scale studies have been carried out on the prevalence of Panic Disorder with and without agoraphobia (Bourdon et al., 1988, Myers, Weissman, Tischler, et al., 1984; von Korff, Eaton, 1989; von Korff, Eaton, & Keyl, 1985; Wittchen, 1986). Other investigations have been carried out into the prevalence of panic attacks *per se* (Margraf & Ehlers, 1988; Norton et al., 1986; Norton et al., 1985). Taken together, these studies are comprehensive and representative enough to allow some confidence in current estimates of prevalence and demographic factors.

Bebbington (personal communication) described epidemiological studies as being an exercise in "counting swans on the lawn." There is some value in doing so, but the exercise does not necessarily give accurate information as to how the swans got there and what might happen to them subsequently. Instead, the preoccupation tends to be with deciding whether swans are truly present or whether they may be particularly attractive ducks. In panic, as in most areas, there are few longitudinal studies which might help provide more definitive clarifications of issues of mechanism. Cross-sectional studies cannot provide unambiguous information in this respect, as they are vulnerable to cohort effects, in which changes in prevalence and comorbidity in different age groups reflect samples subject to variations in critical influences and naturally occurring selection processes.

6.18.3.1 Panic Attacks in Nonclinical Populations ("Nonclinical Panic")

Norton et al. (1985) found that, as measured by questionnaire, 34.5% of 186 students screened had experienced a panic attack in the preceding year, and that 2.2% had experienced at least three such attacks in the preceding two weeks. In a second questionnaire study with some methodological refinements, Norton et al. (1986) obtained figures of 35.9% and 3.1% for the same criteria as in the earlier study, this time among a sample of 256 students. Margraf and Ehlers (1988) conducted two studies intended to replicate the findings from Norton's group in a German sample, to determine the validity and reliability of the questionnaire method as compared to structured clinical interview methodology, and to evaluate the response of nonclinical panickers to laboratory procedures. Margraf and Ehlers were able to replicate the questionnaire results in both of their studies, obtaining higher rates for the year prevalence of panic (46% and 59%) and similar rates for three panic attacks in three weeks (2% and 1%). However, analysis of agreement between questionnaire and interview data indicated that the questionnaire tended to be systematically overinclusive, and that many (approximately 50%) of those identified by the questionnaire as panickers had a milder, subthreshold variant of the problem as assessed by interview. The differentiation of nonclinical panic vs. Panic Disorder presents a number of problems of definition and comparability; nevertheless, as a paradigm for the investigation of the processes involved in panic attacks, it seems particularly promising, especially if there is a psychological dimension underpinning both infrequent panic in normal subjects and frequent panic in Panic Disorder as proposed above. That is, the former may be a milder version of the processes involved in the latter. In studies carried out by both the German group and the Norton group, it has been found that the characteristics of the nonclinical panickers were similar to those identified in clinical samples with respect to the response to procedures such as lactate infusions and scores on questionnaire measures of cognition and avoidance, and so on.

6.18.3.2 Panic Disorder

The largest and most influential studies are those carried out as part of the Epidemiologic Catchment Area (ECA) surveys, carried out in five centers in the USA. Area probability samples (i.e., samples intended to be representative of the characteristics of the populations as a whole) of 3000 people were selected at each site (i.e., a total of 15 000 people). Response rates of 75–80% were obtained; subjects were interviewed using an instrument called the Diagnostic Interview Schedule (Eaton, Holtzer, von Korff et al., 1984). Different levels of definition were employed; the simplest, six-month prevalence of panic, provided figures consistent with Margraf and Ehlers's (1988) nonclinical panic findings (28.5–31.1%; von Korff & Eaton, 1989). Panic Disorder prevalence rates were higher than those previously (6.3–10.0% in the ECA study compared to Weissman's figures of 3.3–6.8%) (Weissman, Leaf, Blazer, Boyd, & Florio, 1986). It is possible that the discrepancy may arise from the use of lay interviewers in the ECA study. Nevertheless, epidemiological studies are consistent in placing the prevalence of Panic Disorder in the general population at around 5%.

6.18.3.3 Correlates of Panic Disorder

As noted above, the factors found to be associated with Panic Disorder also tend to be found in nonclinical panickers. Panic Disorder is more common among women (75% of sufferers). Panic attacks are most likely to develop in the age range 18–24 years, while Panic Disorder is most likely to peak in the age range 24–44 years (von Korff & Eaton, 1989); this finding might indicate that panic attacks represent a precursor to the full disorder. Onset of Panic Disorder is associated with negative life events such as marital conflict and bereavement (Pollard, Pollard, & Corn, 1989).

Boyd (1986) analyzed ECA data across a range of diagnoses, and found that people with Panic Disorder were more likely to seek help for their problem than those with any other psychiatric diagnoses (including schizophrenia). The high prevalence of panic, both in other anxiety disorders and in affective disorders as noted by Barlow (1988), Barlow and Craske, (1988), and Barlow et al. (1985), has been proposed as a factor influencing the decision of these other groups to seek professional help (Barlow, 1988). Boyd (1986) suggests that the strong element of somatic sensations and fears of associated catastrophes might account for consultation. Work by Katon (Katon, 1984; Katon, Vitaliano, Russo, Jones, & Anderson, 1987) provides some support for this view. He noted that early presentation of panic to primary care physicians focused almost exclusively on somatic symptoms (Katon et al., 1987), and that physical causes were initially attributed in 89% of a sample of panic cases; misdiagnoses persisted "for months or even years" (although exact figures are not given).

The association between somatic diagnoses and panic is well known, particularly in the cardiac clinic (Skerrit, 1983; Waxler, Kimbiris, & Dreifus, 1971). The involvement of chest physicians in this area has led to a search for pathophysiological correlates of chest pain and other cardiac symptoms; most commonly, this has focused on the role of hyperventilation, with a diagnosis of "hyperventilation syndrome" frequently being advocated (e.g. Lum, 1976; Magarian, 1982). This is discussed in greater detail below.

6.18.3.4 Comorbidity

The coexistence of panic with a wide range of other psychiatric diagnoses has been noted, particularly by Barlow (Barlow & Craske, 1988; Barlow et al., 1985). Panic attacks occur in between 83% and 100% of patients with anxiety disorders and in those with depressive disorders; the lowest figure tending to be for Generalized Anxiety Disorder (Barlow & Craske, 1988). Strict *DSM-III* diagnoses of Panic Disorder range from rates of 30–50% in major depression (Leckman, Weissman, Merikangas, Pauls, & Prusoff, 1983; Vermilyea, 1987, cited in Barlow, 1988) to 83% in anxiety disorders (Barlow et al., 1985). There were few differences between the characteristics of panic in Panic Disorder groups and the other diagnoses. The report of dizziness and fear of going crazy or losing control were significantly higher in the Panic Disorder patients, a finding which may be of specific relevance to psychological hypotheses which emphasize bodily sensations and their misinterpretation signs of catastrophe. Boyd (1986) has reported high rates of panic in patients diagnosed as part of the ECA study; especially striking in this study are the panic comorbidity figures of 28–62% in schizophrenia.

From a different perspective, panic has usually been described in association with a number of clinical phenomena, particularly avoidance behavior and agoraphobia. It has been suggested elsewhere (Salkovskis, 1988a) that the definition of avoidance behavior associated with panic attacks needs to be broadened to include more subtle aspects of avoidance behavior, particularly the immediate reactions to panic such as holding on to supermarket trolleys, using distraction and so on.

A further likely association is with health anxiety or hypochondriasis, dealt with in greater detail below. The structure of the interview for *DSM-III* is such that hypochondriasis is not classified as an Anxiety Disorder, but instead is part of the Somatoform Disorders Group. For this reason, Barlow et al. (1985) did not include screening for hypochondriasis in their study of the prevalence of panic in other disorders, and this has not yet been evaluated in any other study. From a somewhat different perspective, Noyes, Reich, Clancy, and O'Gorman (1986) used a measure of Hypochondriasis (Pilowsky's Illness Behaviour Questionnaire (IBQ)) and found that scores of 60 patients with Panic Disorder and Agoraphobia were similar to norms obtained from groups of Hypochondriacal patients. In the same study, good treatment outcome in respect of panic was associated with a significant improvement in IBQ scores. One of the main reservations of this study concerns the use of the IBQ, which is a poor measure of hypochondriasis.

6.18.3.5 Natural History of Panic

The absence of high-quality longitudinal studies means that little is known definitively about the natural history of panic and Panic Disorder. In general, it appears that, in some patients, an anxiety diathesis is present in childhood and that chronicity is common (Degonda & Angst, 1993; Pollack et al., 1990; Pollack & Otto, 1997). Most information comes from cross-sectional studies, and is subject to a range of problems such as cohort effects. As outlined above, there is some evidence that panic attacks precede the development of Panic Disorder. Von Korff and Eaton (1989) make an interesting theoretical case for Panic Disorder as a sequenced and staged problem. The sequence proposed is based on that suggested by Klein et al. (1987), and runs as follows:

(i) occurrence of panic attacks;
(ii) cognitive appraisal of symptoms as harmful;
(iii) sensitization to symptoms; and
(iv) development of avoidance.

These stages are said to represent different phases in the development of a disease. Agoraphobia is thus said to represent a later stage of Panic Disorder. The evidence supporting this epidemiologically-based view is scanty and, in some instances may be contradictory. For example, Thyer, Nesse, Cameron, and Curtis (1985) demonstrated that, in their sample, Panic Disorder patients have a (nonsignificantly) *longer* duration of disorder compared to agoraphobics. The disease-stage model would predict a significantly shorter duration. The link between Panic Disorder and Agoraphobia is discussed in detail in Salkovskis (1988a); it is concluded that the data is consistent with two possibilities; either that important idiosyncratic individual differences in the reaction to anxiety and panic may be involved, or that there may be a difference in severity, with agoraphobia with panic representing the more severe variant (Pollack & Smoller, 1995).

A further shortcoming of the disease-stage model is the implication of a passive relationship between panic and avoidance such that avoidance is *caused by* panic. There is a considerable amount of data supporting Marks (1987a, 1987b) assertion that a functional relationship exists between agoraphobia and panic and vice versa; not least is the demonstration that exposure treatments not only reduce avoidance but also ameliorate panic attacks (Marks et al., 1983; see also review in Michelson, 1988). Again, all concerned conclude that the requirements for longitudinal studies are paramount (Klein et al., 1987; Marks, 1987a).

6.18.3.6 Other Issues

There are a range of other issues relevant to the phenomenology and assessment of panic attacks and Panic Disorder; these are reviewed in Barlow (1988), Rachman (1990), and Salkovskis (1988a). The main questions posed can be summarized as follows:

(i) Is panic qualitatively distinct from other forms of anxiety?

(ii) Is there a dimensional basis for panic, with the presence of Panic Disorder reflecting an extreme score on an underlying psychological dimension; if so, what is the nature such a continuum?

(iii) Is there a difference between cued and uncued ("spontaneous") panic attacks?

These issues have not been fully resolved (Salkovskis, 1988a); however, it now seems most likely that the answers to such questions will depend less on epidemiological and phenomenological studies and more on experimental investigations based on the evaluation of particular theories of the nature of panic.

6.18.4 THEORIES OF PANIC

There are two main approaches to the conceptualization of panic attacks. These are:

(i) Biomedical hypotheses, which consider that Panic Disorder is an illness or disease with a specific pathophysiology (caused by a lesion, a biochemical deficiency, or some other abnormality of structure or function). These hypotheses include Klein's original position, his suffocation-alarm hypothesis, Charney's neuropharmacological hypotheses, Leibowitz et al.'s detailed neuroanatomical hypothesis, and the physiological/hyperventilation syndrome theories of Lum and Ley.

(ii) Psychological hypotheses, which propose that panic is the outcome of normal processes which may be quantitatively but not qualitatively different from everyday experience. These include van den Hout's interoceptive conditioning hypothesis and the cognitive hypotheses advocated by Beck, Clark, Ehlers, and Salkovskis. Barlow's "false alarm" hypothesis is described here as psychological because many of the processes invoked are psychological in nature. However, it also shares a key characteristic with the biomedical hypothesis in that it starts from the supposition of dysfunction in a biological "alarm" mechanism which determines the uniqueness of panic.

As Seligman (1988) and Rachman (1990) comment, the debate between the two positions concerning panic has considerable implications in other areas, being the "centerpiece" of the debate between two competing models of psychopathology.

Despite the major redefinition which was involved in *DSM-III*, earlier behavioral conceptualizations of phobic anxiety and Agoraphobia remain of vital importance (cf. Marks, 1987a; Salkovskis & Hackmann, 1997) and have much to say about the implications of phobic avoidance behavior (particularly agoraphobic avoidance and its treatment). However, at this point behavioral theories have not directly contributed to the debate on the nature of panic, and for a variety of reasons tend to become aligned with cognitive views in the form of cognitive-behavioral approaches (Hawton, Salkovskis, Kirk, & Clark, 1989; Salkovskis, 1986). For detailed accounts of older behavioral approaches to the understanding of agoraphobic behavior, the interested reader is referred to Foa et al. (1984), Hallam, (1978, 1985), Marks (1981, 1987b), Mathews, Gelder, and Johnston (1981), and Rachman (1990).

6.18.4.1 The Original Biological Hypothesis: Klein's View

The importance of Klein's hypothesis goes beyond its intrinsic value, both because it resulted in the adoption of pharmacotherapy as the dominant North American treatment approach to panic and because other biological theories which developed later have tended to take his views and evidence as their own starting points. For this reason, the foundations of this theory will be considered particularly carefully. Klein (1980, 1981; Klein & Klein, 1988, 1989a, 1989b) argues that several findings indicate a qualitative distinction between panic anxiety and anticipatory or phobic anxiety. These are: (i) the apparently spontaneous nature of some panic attacks; (ii) the observation that panic but not anticipatory anxiety responds to antidepressant medication (Sheehan, 1982), and that panic does not respond to phenothiazines or (as shown later) benzodiazepines; (iii) the finding that patients have experienced more separation anxiety and school "phobia" (50%) than mixed psychiatric controls who were not diagnosed as suffering from Panic Disorder (27%) (Gittleman-Klein & Klein, 1984; Klein, 1964); (iv) the finding that sodium lactate frequently precipitates panic attacks in Panic Disorder patients but does not do so as frequently in nonclinical control subjects or socially anxious patients (Liebowitz et al., 1984; Liebowitz, Fyer, et al., 1985; Pitts & McClure, 1967); (v) evidence of a familial (possibly genetic) component in panic; particularly the higher concordance rate for panic in monozygotic as compared to dizygotic twins (Crowe, Pauls, Slymen, & Noyes, 1980; Torgerson, 1983).

Klein regards panic as similar to epilepsy, with uncontrolled discharges of activity in the biobehavioral anxiety system producing semi-random bursts of activity which manifest as panic attacks. This is said to happen because a normally stabilizing negative feedback loop has become converted to a pathological positive feedback loop, possibly as a result of sensitizing separation experiences during childhood. All other panic-related phenomena follow on from these bursts of pathological activity, including Agoraphobia (Klein et al., 1987).

Klein's position has been criticised as being too vague, especially in terms of the failure to specify the exact nature of the disordered mechanism (Rachman, 1990). There have been a variety of critiques of the evidential basis of Klein's theory; these are fully discussed in Clark (1986a, 1986b, 1988), Margraf, Ehlers, and Roth (1986), Rachman (1990), and Barlow (1988). In the order specified above, these can be summarized as follows.

(i) The degree of spontaneity of panic, even early attacks, is debatable; in the longer term, work such as that reported by Faravelli (1985), Finlay-Jones and Brown (1981), Pollard, Pollard, and Corn (1989) and reviewed in Roy-Byrne and Uhde (1988) indicates that threat-related life events tend to precede the onset of panic. In more immediate terms, there is evidence that acute panic is often preceded by identifiable stimuli such as bodily sensations and frightening thoughts (Beck, Laude, & Bonhert, 1974; Hibbert, 1984). These interview studies have received support both from studies 24 hour ambulatory psychophysiological monitoring (reviewed in Freedman, 1989) and from work using telemetry and computer based *in situ* questionnaires (Taylor, Fried, & Kenardy, 1990).

(ii) The initial supposition (Klein & Fink, 1962) that phenothiazines were specifically anxiolytic in generalized anxiety has not been supported by subsequent research. In later work, the emphasis of the "pharmacological dissection" shifted to the demonstrably anxiolytic benzodiazepine class of drugs. Early studies suggested that the benzodiazepine class of drugs were not effective in the treatment of panic attacks (McNair & Kahn, 1981), whilst a range of outcome studies continued to provide evidence for the specific efficacy of tricyclic antidepressants (Garakani, Zitrin, & Klein, 1984; McNair & Kahn, 1981; Zitrin, Klein, Woerner, & Ross, 1983). However, there is now a considerable amount of evidence available for short-term (i.e., over a period of six weeks) beneficial effects of benzodiazepine administration in panic, particularly the triazolobenzodiazepine alprazolam (Ballenger et al., 1988), but also to higher doses of more conventional benzodiazepines such as diazepam (Noyes et al., 1984). However, the efficacy of imipramine as an effective treatment for Panic Disorder is now well established (Ballenger, 1986; Sheehan, Ballenger, & Jacobsen, 1980). Despite Marks' assertion that the antipanic effects of imipramine are mediated by its specific antidepressant action (based on the results of the study carried out by Marks et al., 1983; see also Marks, 1987a), this conclusion is not supported by a large number of other well-conducted studies (Clum & Pendrey, 1987; Klein & Klein, 1989a, pp. 151–153). The more convincing reservation (Telch, Tearnan, & Taylor, 1983) focuses on whether or not the effectiveness of imipramine is *independent* of the self-exposure instructions which invariably accompany pharmacological treatment. The effectiveness of such instructions on their own and combined with pharmacological treatments has been the subject of much investigation. At present, there is some evidence that the effects of imipramine and self-exposure instructions might be synergistic (Margraf & Ehlers, 1989; Telch et al., 1983). Finally, a number of authors have pointed out that the effectiveness of a particular treatment modality (i.e., biological or psychological) is not convincing evidence favoring the basis of a disorder in that modality (Clark, 1988; Rachman, 1990).

(iii) A number of carefully controlled studies (including prospective ones) have failed to find differences between panic patients and others in terms of separation anxiety and school phobia (Berg, Butler, & Pritchard, 1974; Coyrell, Noyes, & Clancy, 1983; see also reviews by Margraf, Ehlers, & Roth 1986a, 1986b, and Tearnan, Telch, & Keefe, 1984). Earlier assertions in this respect were largely based on retrospective reporting.

(iv) 40% or more of panic patients do not panic when sodium lactate is administered. This observation is not consistent with the hypothesis that response to lactate is a specific "biological marker" for the mechanisms involved in naturally occurring panic attacks. Data from the Oxford group indicates that, far from being impervious to psychological influences as previously argued (Klein, 1981), the anxiety-provoking effects of lactate in panic patients can be blocked by instruction (Clark et al., in preparation). A further problem for Klein's original position is the fact that sodium lactate infusions are only one of a range of "biological challenges" which have the effect of provoking panic attacks in Panic Disorder patients; the range of such panic-provoking challenges is remarkably wide, including adrenaline, caffeine, increased carbon dioxide, hyperventilation, isoproterenol, *m*-CPP, and yohimbine (see reviews by van den Hout & Griez, 1986; Margraf, Ehlers, & Roth, 1986a, 1986b); Uhde & Tancer, 1989). The importance of the finding that all of these diverse provocations produce a panic response in panic patients is the fact that these challenges have not been identified as having any commonality in terms of either their biochemical or physiological effect. Thus, it is very unlikely that they are all working on the same mechanism, and no view has yet been proposed concerning possible multiple inter-related influences involved in the biochemical triggering of panic. It is therefore not clear whether some biochemical inductions are valid models of naturally occurring panic and others are not, whether none are, and so on. As will be described below, a psychological account best encompasses the full range of inductions used, and does so in a particularly parsimonious way.

(v) The evidence for a familial component is relatively stronger than other evidence for the biological hypothesis (Kendler, Heath, Martin, & Eaves, 1987). However, there are some distinct oddities in the concordance data which are difficult to make sense of from the standpoint of a genetic diathesis for the occurrence of panic attacks. For example, groups of relatives who should show similar genetic risk have been shown to have widely differing rates of panic and other anxiety disorders. Dizygotic twins were shown by Torgersen (1983) to have lower panic concordance rates than nontwin siblings, and concordance between siblings is less than between parents and children (Moran & Andrews, 1985). The extent to which familial risk for Panic Disorder differs from that for Generalized Anxiety Disorder is a subject of debate (Margraf et al., 1986a, 1986b). Margraf and others have suggested that concordance rates are only high for panic when liberal diagnostic criteria are used (i.e., when the presence of panic is recorded because of what are described as limited symptom attacks [increases in anxiety involving less than the four symptoms required by *DSM-III*]) as opposed to the full diagnostic criteria for Panic Disorder. That is, it is not possible to rule out the suggestion that relatively mild symptoms of general anxiety are being inappropriately identified as panic attacks. This view is consistent with the findings that those studies finding the highest concordance for panic also find the lowest concordance for Generalized Anxiety Disorder. Barlow (1988, pp. 172–174) summarizes this data, and proposes that the evidence on the heritability of anxiety is most consistent with the hypothesis of the *trait* of anxiety (often described as emotionality, nervousness, or neuroticism). He argues that studies reporting a difference between heritability for Panic Disorder and other anxiety disorders have not controlled for the fact that all Panic Disorder subjects are generally anxious with different levels of severity which are inherent in the structure of the *DSM-III* diagnostic rules. When severity of disorder is taken into account, Barlow points out that the different anxiety disorders appear to be equally heritable.

In later theoretical writings, Klein and Klein (1989a, 1989b) suggest that the specific mechanism of panic may involve an evolutionarily evolved central alarm mechanism which functions in relation to separation anxiety or impending asphyxia, and that catastrophic cognitions are incidental to this biological mechanism. He argues that "Many spontaneous panics occur when the brain's suffocation monitor erroneously signals a lack of useful air, thereby maladaptively triggering an evolved suffocation alarm system" (Klein, 1993; see also Klein, 1996). Again the suggestion is that panic is relatively impervious to psychological influences. The evidence against the "irrelevance" of psychological influences is now overwhelming. There have been a number of more direct tests of the suffocation/alarm system which suggest that it is not correct (e.g., Taylor, Woody, Koch, McLean, et al., 1996).

6.18.4.2 The Neuroanatomical Hypothesis

A group of researchers from Klein's center proposed a "neuroanatomical hypothesis," which they describe as being inspired by his work (Gorman, Liebowitz, Fyer, & Stein, 1989). This complex hypothesis takes Klein's basic assertions (p. 26) as its starting point, but attempts both to make the position more explicit and to identify the neuroanatomical basis of the components of the hypothesis. The paper also attempts to incorporate cognitive-behavioral findings and circumvent the psychological/biological debate described above (p. 25). They argue that it is not useful to attempt to specify whether panic is "a behavioural cognitive disease" (sic) or "a biological disease," and that it should be regarded as having elements of both. By describing the basis of their hypothesis in this way, they seem to misconstrue the basis of the debate, which is not biological vs. psychological, but disease vs. nondisease (Rachman, 1990). The neuroanatomical hypothesis proposes that:

> there are three distinct components of the illness Panic Disorder—the acute panic attack, anticipatory anxiety and phobic avoidance. These three clinical phenomena arise from excitation of three distinct neuroanatomical locations, respectively: the brainstem, limbic lobe, and prefrontal cortex. Reciprocal innervation among nuclei in these three centres explains the genesis of the disease and its clinical fluctuations over time. (Gorman et al., 1989, p. 149)

Like Klein's view, the model proposed is a disease-stage one, with acute panic being the necessary first stage, followed by the development of anticipatory anxiety and agoraphobic avoidance. The problem of the development of agoraphobia without preceding panic attacks is acknowledged (Gorman et al., p. 149) but not dealt with except by suggesting that "phobic avoidance and anticipatory anxiety could conceivably be maintained without the induction of panic if only these reciprocal pathways between prefrontal cortex and limbic areas were involved" (Gorman et al., p. 156). Gorman *et al.* specify that the complexity of the hypothesis means that a great many experiments will be required to validate or disprove the model; they also argue in their conclusion that, because the disorder is complex and involves so many facets, it requires a complex theory to account for it (p. 158). Perhaps the principal problem with this position is the fact that they do *not* specify any differential predictions vis-à-vis alternative hypotheses, relying instead on a proposed synthesis which incorporates alternative accounts ("combined rather than opposed," p. 158). However, they do insist on the basic assumption of "the neural circuits of the brain as the basis for pathology."

The argument for a brainstem basis of acute panic is based on the physical character of panic symptoms and the biochemical panic provocation studies discussed above in the context of Klein's theory. The suggestion is that the various panic-provoking agents produce paroxysmal brainstem activity as a result of activity in one or more specific brainstem loci. However, the central basis of at least one panic-provoking agent, isoproterenol (which provokes panic at the same rate as lactate infusions; Rainey et al., 1984), is particularly hard to explain in these terms as it does not cross the blood–brain barrier (Conway, Tejani-Butt, & Brunswick, 1987) and therefore cannot have its panic-provoking effects as a result of direct action on the brainstem. Gorman et al. discuss yohimbine as an exemplar of a panic-provoking agent because its action is relatively well understood; it has the effect of increasing CNS noradrenergic activity, particularly in the locus coeruleus and pontine nucleus. The effect of yohimbine in activating the brainstem noradrenergic activity which is hypothesized to be implicated in panic is described in some detail (Gorman et al., p. 156). The role of clonidine, which has the opposite effect to yohimbine on noradrenergic activity, is more briefly alluded to; two studies of the effects of clonidine in panic patients are cited as additional evidence of the proposed noradrenergic hypersensitivity in panic patients (Charney & Heninger, 1986; Nutt, 1986). However, as is described below (p. 39), although the results of these clonidine studies appear to show an abnormality, it is *not* consistent with a simple hypersensitivity as proposed by the neuroanatomical model.

The evidence for a link between the limbic system ("limbic lobe") and anticipatory anxiety is somewhat more consistent, being mainly derived from the work of animal researchers such as Gray (1982). The specific involvement of this system in Panic Disorder in man is more difficult to justify. Little evidence supporting such a link is presented, other than general allusions to the vulnerability of the limbic system to the generalization of spasmodic CNS electrical activity ("kindling effects") coupled with speculation that general anxiety associated with panic might result from such kindling effects. The importance of the limbic system to the neuroanatomical model is related in large part to the proposition that it is through this system that nonpharmacological interventions (particularly exposure) have their effects. It is difficult to see how the propositions made concerning the role of limbic system can be evaluated directly, and whether this component of the hypothesis in any way advances the understanding of mechanisms involved in panic attacks and their treatment.

The prefrontal cortex is linked to panic and anticipatory anxiety by its presumed cognitive function; it is here that interpretations are linked to brainstem discharge, according to the model. The extensive innervation (afferent and efferent) of this area is said to make it particularly suitable for such a function. Again, no specific evidence in support of a link with panic is offered other than previous general studies into the possible function of the prefrontal cortex. If this aspect of the hypothesis is correct, then it may be possible to evaluate this directly by experiments involving patients who have previously been subject to psychosurgery in this region.

Perhaps the most valuable aspect of Gorman et al.'s paper is that it offers specific predictions which are said to allow experimental testing of the hypothesis. These predictions generally specify the likely locus of brain activity which should accompany various forms of stimulation and treatment. The prediction which is particularly relevant to psychological hypotheses concerns treatment, specifically that cognitive-behavioral treatments will leave a core of occasional panic attacks (whilst drug treatments will not) because cognitive-behavior therapies "exert ameliorative effects at a different 'site' of disease progression than do antipanic drugs" (Gorman et al., p. 157). This proposition already seems to have been invalidated (Clark et al., 1994; Clark, Salkovskis, & Chalkley, 1985; see also below).

Altogether, the neuroanatomical hypothesis is disappointing in that it does not utilize new data, and seems to explain less than Klein's original hypothesis. The attempted integration is unhelpful because it retains the basic proposition of a disease process, and because psychological factors are only included in the account as secondary phenomena to the unmodified "fact" of biologically determined panic. That is, all psychological factors are considered to operate "downstream" of fundamental biological mechanisms modifying the secondary response to panic itself, with the most minimal of interactions even at this secondary level. This position does not take account of the wide range of psychological findings described below. The problems associated with the empirical foundations of Klein's position (described above) remain unresolved by this newer theorizing.

6.18.4.3 Neurochemical Hypotheses: Noradrenaline and the Locus Coeruleus

Some of the most scientifically interesting work on biological approaches to panic has emanated from Charney's group (Charney & Heninger, 1986), who have concentrated on a neurochemical hypothesis in which it is proposed that panic attacks are a result of dysregulation in the noradrenergic system. This work formed an elaboration of earlier basic research in primates implicating the locus coeruleus (LC) in fear situations and behaviors. Redmond and colleagues found that direct stimulation of the LC in stump-tailed monkeys results in a behavioral response said to mimick a human panic attack; the monkeys displayed behaviors characteristic of fear in the wild (e.g., scratching and grimacing) (Redmond, 1985; Redmond & Huang, 1979). Ablation of the LC in monkeys was associated with less fear responses when in the presence of anxiety-provoking stimuli, as was the administration of many antianxiety drugs (Redmond, 1979; 1985; Redmond & Huang, 1979). Charney and Heninger (1986) argue that the importance of the noradrenergic LC system lies in its responsivity to sensory input and the ramifications of this system throughout the cortex. They propose that "abnormally high responsivity of brain noradrenergic systems is etiologically related to the development of panic disorders." In particular they focus on the possible importance of alpha2-adrenergic presynaptic receptors (autoreceptors), which regulate the release of noradrenaline within their own neurones through a negative feedback mechanism. Charney proposed that impairment of this inhibitory mechanism leads to inappropriate paroxysmal discharges in the arousal system in response to low levels of stimulus input. Evidence for this position was derived from the fact that some panic-inducing substances, such as yohimbine and caffeine, are known to stimulate the LC, while drugs which have an antipanic effect are known to depress LC activity (e.g., tricyclic antidepressants; but also diazepam).

There are a number of problems with the LC hypothesis. There are doubts about the generalizability of much of the animal research upon which it is based (Mason, 1981), and a variety of findings from well-conducted studies contradict the earlier positive results. For example, biochemically specific noradrenergic LC lesions in rats do not impair the response to threatening stimuli (File, Deakin, Longden, & Crowe, 1979) and do not impair the acquisition of one-way, two-way, and Sidman avoidance responses, nor modify conditioned suppression. In humans, the effect of LC and central noradrenergic disturbances are impaired perceptual organization and memory, disorientation, hallucinations and delusions, with anxiety not being a prominent feature (van Dongen, 1981). Drugs such as buspirone and carbamazepine which increase LC activity and mianserin which blocks the activity of alpha2-autoreceptors do not induce panic, and have been shown to be therapeutic in some instances. The evidence for Charney's LC hypersensitivity hypothesis is not particularly convincing. However, this line of research has generated a series of findings in panic patients which are not readily explained by any other position, and which suggest some biological differences between panic patients and nonclinical subjects. Charney and Heninger (1986), Nutt (1986), and Uhde, Siever, and Post (1984) evaluated the response to the alpha2-receptor agonist clonidine in panic patients and nonclinical controls. They found that panic patients show a modified hormonal response (significantly greater decreases in the noradrenergic metabolite MHPG (3-methoxy-4-hydroxyphenylglycol) and smaller increase in growth hormone) and greater decreases in blood pressure (but not heart rate). While these differences cannot satisfactorily be explained in any detail by the LC hypothesis as originally stated, they might indicate what Charney describes as a "dysregulation," involving both over- and under-responsiveness of different subsystems, perhaps even the same subsystems at different times. This line of research may be of interest if it can be shown that the key results can be replicated when panic patients are compared to anxious controls.

6.18.4.4 Physiological Accounts of Panic: Panic as a "Hyperventilation Syndrome"

The notion that panic attacks may occur as a result of episodic hyperventilation is an old one which has recently been enthusiastically revived

(Hibbert, 1984; Ley, 1985a, 1985b). It has periodically been suggested since the 1930s that the physiological effects of breathing in excess of metabolic requirements could account for sudden severe attacks of anxiety accompanied by a wide range of bodily sensations (e.g., Gibson, 1978; Kerr, Dalton, & Gliebe, 1937; see also review by Magarian, 1982). Briefly, the hyperventilation hypothesis is that, under conditions of stress, patients breathe in an excess of metabolic requirements, that is, they breathe out more CO_2 than they produce. When this happens, it results in a "blowing off" of CO_2. That is, because of the more rapid movement of air in and out of the patient's lungs, more CO_2 than usual diffuses out of the pulmonary blood vessels and into expired air, resulting in a drop in the partial pressure of arterial CO_2 (p_aCO_2). Because CO_2 is dissolved in blood as carbonic acid (as part of the pH buffering system), the effect of decreased p_aCO_2 is an increased alkalinity of blood, usually described as a "respiratory alkalosis." In physically healthy subjects, respiratory alkalosis produces a range of physical sensations, potentially including most of those regarded as symptoms of panic. Thus, it has been argued that panic attacks are caused by or are even synonymous with episodes of acute hyperventilation.

Normally, respiratory alkalosis is self-correcting, in that respiration self-regulates; lowered p_aCO_2 results in the activation of a range of negative feedback mechanisms, such as increased tone in the chest wall (intercostal) muscles. Note that increased breathing rate or depth are not necessarily indicative of hyperventilation; only blood CO_2 levels (as measured directly from arterial blood [p_aCO_2] or the mixed venous [$p_{mv}CO_2$] systems) give true indications of whether hyperventilation is occurring or not, and the degree to which it is present. It also appears that it is not the absolute level of p_aCO_2 which is important, but is instead the extent to which this variable shows a rapid decrease. This has been shown in an elegant way by Hout van den and Griez (1985), who carried out an experiment on breath-holding after CO_2 inhalations. They demonstrated that the symptoms induced by inhalations of 35% CO_2 in 65% O_2 did not arise from the increased carbon dioxide associated with the inhalation, but by the subsequent rapid *fall* which occurs when an inhalation is released and followed by a reflex hyperventilation and unusually large decrease in p_aCO_2. (See Hardonk & Beumer, 1979, and Lum, 1976, for more detailed accounts of physiological factors involved in hyperventilation; Hibbert (1984) provides a concise account of the simplest form of the hyperventilation hypothesis of panic attacks.) The role of change in p_aCO_2 levels in the production of symptoms has also led to a specific proposal concerning the role of hyperventilation in the vulnerability to acute episodes of panic symptoms. It has been proposed that panic patients are vulnerable to such acute episodes of panic arising from hyperventilation because of a chronic, asymptomatic hyperventilation (Lum, 1976). Thus, it is argued that frequent hyperventilation leads to the blood buffering system "resetting," so that a constantly lowered p_aCO_2 is present at all times, but only becomes symptomatic when a further acute drop occurs, which will occur relatively frequently because the reset buffering system is more reactive to small p_aCO_2 changes.

Hyperventilation therefore provides an apparently simple and clinically appealing explanation of an otherwise complex and perplexing phenomenon, and this type of hypothesis has enjoyed intermittent popularity and "rediscovery" every few years. The recently renewed attention to the proposed link between panic anxiety and respiration probably arises from the emphasis currently placed on the diagnostic importance of panic attacks and the search for biological explanations and treatment already described above. This is because explanations based on the idea of "hyperventilation syndrome" invariably have an implicit basis in biomedical ideas of underlying dysfunction or pathology of respiratory control.

6.18.4.4.1 Evidence for an association between panic and hyperventilation

The evidence for an association between panic and hyperventilation is considerable. However, this falls far short of evidence for causation. First, it has frequently been observed that voluntary hyperventilation reproduces symptoms similar to those experienced during panic attacks, including increased anxiety (e.g., Lum, 1976). Second, substantial drops in p_aCO_2 levels have been observed as a result of contrived and naturally occurring stressors in panic patients (Hibbert, 1986; Salkovskis, Clark, & Jones, 1986; Salkovskis, Warwick, Clark, & Wessels, 1986) and in normal subjects. Third, a number of studies have reported that panic patients have significantly lower resting levels of p_aCO_2 than normal controls (Gorman et al., 1987; Gorman et al., 1986; Rapee, 1986; Salkovskis, Jones, & Clark, 1986), possibly indicating the occurrence of renal compensation for repeated acute hyperventilation ("resetting" of the buffer system; Gledhill et al., 1975). That is, if hyperventilation (and therefore the respiratory alkalosis) is prolonged, the metabolic response involves excretion of bicarbonate, which restores the acid/base balance at a lower level of p_aCO_2. Fourth, respiratory symptoms and fears are particularly prominent among panic patients (Pollard, 1986) and symptoms associated with hyperventilation are significantly more likely to occur in panic patients than in patients suffering from general anxiety disorder (Rapee, 1985). Finally, there have been a number of reports of the success of treatments which contain an element of respiratory control (Clark et al., 1985; Lum, 1976; Salkovskis, Jones, & Clark, 1986), and that successful psychological and physical treatment results in a significant decrease in resting p_aCO_2 (Gorman et al., 1987; Salkovskis & Clark, 1986).

6.18.4.4.2 Hyperventilation as a CAUSE or EFFECT of panic

Ley (1985a, 1985b) strongly argues that hyperventilation causes panic. In a formulation very similar to previous "hyperventilation syndrome" hypotheses (Garssen, van Veenendaal, & Bloemink, 1983; Hardonk & Beumer, 1979; Lum, 1976), he proposed that "the panic attack is unique, that it consists of a synergistic interaction between hyperventilation and fear" (Ley, 1985b, p. 272). The basis of the relationship between fear and hyperventilation is said to be found in the way in which fear activates the sympathetic nervous system and thence drives the intercostal muscles of the thorax, thus increasing respiration. Ley regards the occurrence of hyperventilation as the crucial (necessary) factor for panic to occur, and states that "the crucial assumption is that *sensitive* individuals who have recently experienced stressful events are constantly overbreathing and, therefore, on the brink of respiratory alkalosis" (Ley, 1985b, p. 281).

The foundations of this approach do not substantially differ from other attempts to account for panic attacks as part of a centrally determined defect of respiratory control. As with previous statements of the hyperventilation hypothesis, the way the role of fear is dealt with presents some problems, although it is at least considered in some detail. Fear is said to arise either as a direct physiological effect on the autonomic nervous system, or the intensity of the symptoms in some direct (and unspecified) way produces fear and alarm. An interaction between fear and overall levels of stress and sensitivity to fear is proposed, as well as individual differences in the respiratory system and its reactivity.

Most problematic for the view that hyperventilation is a necessary cause of panic attacks are the results of work on ambulatory monitoring of CO_2. This technique measures the concentration of CO_2 passing across the skin (transcutaneous CO_2) and record the information on a miniaturized belt-mounted recorder while the patient goes about their normal business. This measure of transcutaneous CO_2 has been shown to correlate highly with arterial CO_2 (Pilsbury & Hibbert, 1987). Studies using this measure have shown that some patients do not hyperventilate during panic attacks (Hibbert, 1986; Hibbert & Pilsbury, 1989). The effectiveness of treatment involving elements of respiratory control has been taken as evidence for the hyperventilation hypothesis. Early cognitive treatments emphasized respiratory control as part of a broader program of treatment directed at reattribution. Hibbert and Chan (1989) attempted to replicate the Clark et al. (1985) and Salkovskis, Jones, and Clark (1986) findings for respiratory-based treatment but without the inclusion of a cognitive element; the results of this relatively large study suggest that the effectiveness of previous treatments may have been due to the cognitive element, and is certainly not likely to be accounted for by the physiological basis of respiratory control alone.

Nevertheless, while it is difficult to support the view that hyperventilation causes panic, it is also difficult to maintain the view that acute hyperventilation, when it occurs, is irrelevant to the experience of panic. The differences reported between panic patients and control subjects in resting CO_2 seem certain to result in reduced blood buffering capacity and should have the effect of making panic patients more prone to experiencing substantial respiratory changes in response to relatively minor challenges. In a consecutive series of single-case experiments with panic patients, very substantial drops in p_aCO_2 occurred as a response to mild specific psychological stressors (Salkovskis, Clark, & Jones, 1986, discussed together with other related data in Salkovskis & Clark, 1986). It was concluded in this paper that the rapidity and magnitude of the observed changes in CO_2 were sufficiently large to infer that a symptomatic respiratory alkalosis must at least have contributed to the symptoms experienced. That similar profound changes can be observed in a proportion of naturally occurring panic attacks has been demonstrated by a single case in which it was possible to directly measure arterial p_aCO_2 and pH (Salkovskis et al., 1986) and by a study using ambulatory measures of transcutaneous CO_2 (Hibbert & Pilsbury, 1989). There is evidence from a study on the clinical presentation of anxiety disorders that the main symptoms which trigger thoughts of physical and mental harm in panic patients (but not in generally anxious patients) are the symptoms commonly produced by hyperventilation (Rapee, 1985).

It thus appears that it is not possible to account fully for panic by invoking concepts such as "hyperventilation syndrome," but neither does it seem possible to totally discount a role for hyperventilation in the production of symptoms experienced during panic attacks. The way in which the hyperventilation hypothesis enjoys periodic popularity has been based on the fact that there is indeed compelling evidence of an association with anxiety, and on enthusiastic clinical reports of the efficacy of treatments involving breathing exercises (Lum, 1975, 1976). Any hypothesis must therefore reconcile the strong evidence for an association between hyperventilation and panic with the equally strong evidence that hyperventilation is neither necessary nor sufficient for the occurrence of panic. After reviewing psychological hypotheses of panic, I will return to consider a cognitive explanation of the relationship between panic and hyperventilation.

6.18.5 PSYCHOLOGICAL THEORIES OF PANIC

Although psychological hypotheses of panic are a relatively new development, behavioral theories of agoraphobia have been generating research and treatment studies directly relevant to panic since the early 1960s (see Hallam, 1985; Marks, 1987b; Mathews et al., 1981). Such work continues to generate valuable results, and has become substantially integrated with the more recent research and theory emphasizing panic attacks. Some of the most substantial and important work has approached panic from the perspective of panic attacks associated with phobic behavior (Barlow, 1988; Rachman, 1990).

There are two main psychological hypotheses of panic, both of which draw on a variety of influences. These are interoceptive conditioning models (Barlow, 1988; Hout van den, 1988) which are most closely modeled on theories of classical conditioning particularly Russian work described by Razran (1961) and cognitive theories (Beck, 1988; Clark, 1986a, 1986b, 1988; Salkovskis, 1988a) which are based on Beck's (1976; Beck, Emery, & Greenberg, 1985) cognitive approach to emotional disorders. The discussion of Clark's cognitive model subsumes similar models, particularly the psychophysiological models described by Margraf and Ehlers; as pointed out in Ehlers, Margraf, and Roth (1988), all such theories (with the exception of Barlow's) share common assumptions and differ only in emphasis. No differential predictions have, as yet, been identified for any of these other psychophysiological models which have been proposed to account for cognitive–physiological interactions (Ehlers & Margraf, 1989); Clark's (1986a, 1986b) hypothesis therefore remains the most parsimonious and influential of these.

6.18.5.1 Barlow's Model: False Alarms and Learned Alarms

Barlow's model (Barlow, 1988, 1991) is particularly interesting because it is presented in the context of a major monograph in which he attempts to develop an overarching theory relevant to all anxiety disorders and to synthesise conditioning, neurobiological and psychosocial factors. He acknowledges that the result lacks specificity at times, although he also expresses the hope that it represents a testable set of propositions. Interestingly, the model bears some resemblance to the neuroanatomical hypothesis (p. 32), in that it is a disease-stage model with an emphasis on concepts of malfunctioning subsystems. Unlike other psychological models of panic, Barlow's specifically proposes a qualitative distinction between panic and other forms of anxiety. The basis for the model concerns a "complex biopsychosocial process," involving the interaction between "an ancient alarm system, crucial for survival, with inappropriate and maladaptive learning and subsequent cognitive and affective complications" (Barlow, 1988, p. 209). Thus, a biological (evolutionarily relevant) alarm system is postulated; this primitive system is designed to react to actual danger with a set of energizing responses, termed a "true alarm"; such responses prepare the organism to react in appropriate ways to threat, and are therefore associated with "action tendencies," which are either escape/flight, freezing/immobility, or aggression/attack. However, under conditions of nonfocal threat and consequent generalized hyperarousal (e.g., during a period following a major threat-related life event), biologically (genetically) vulnerable individuals become prone to spontaneous discharges of the alarm system. Specifically, "false alarms" (panic attacks experienced at the outset of development of Panic Disorder) are said to "spike off" from a stress response in such vulnerable individuals. That is, generalized anxiety increases under stress and forms a kind of platform which puts the alarm system on a hair-trigger and makes the sparking off of an alarm-type response particularly likely. This initial occurrence of spontaneous panic as "false alarms," which are said to be characteristic of the panic attacks experienced by nonclinical panickers may, in turn, become conditioned to interoceptive stimuli if a false alarm was associated with such stimuli. The formation of such conditioned associations are particularly likely if the association occurs in a situation where the ability to carry through "action tendencies" is blocked. This conditioning process then results in the occurrence of "learned alarms." For Panic Disorder to result, there is a further crucial step, however. Anxious expectation over the occurrence of negative events or subsequent "alarms" must develop, and is said to be "a crucial psychological vulnerability," possibly arising as a result of a "pre-existing disposition to focus anxiety specifically on somatic events." This tendency would make such individuals "exquisitely sensitive to false alarms." Avoidance and cognitive symptoms seem to follow on in a relatively passive way, although this is not made more explicit than already described except as a diagram in which these are depicted as a noninteracting end-point of the sequence. The lack of emphasis on cognitive factors in the theory contrasts markedly with Barlow and Cerny's (1988) and Rapee and Barlow's (1989) description of treatment, which includes a major component of cognitive intervention.

Barlow does not himself suggest any specific predictions from this model, nor does he differentiate it in this way from other hypotheses. However, he does state that "there should be enough coherence within the theory to enable investigators to design research protocols that result in confirmation or disconfirmation" (Barlow, 1988, p. 209). Perhaps the most striking aspect of his theory for the present thesis is the way in which cognitive factors are regarded as a passive "downstream" consequence of a response to the experience of physiological sensations previously associated with excessive arousal. Cognition is thus seen as a complication of a biologically initiated sequence.

6.18.5.2 The Cognitive Hypothesis of Panic

A cognitive hypothesis of panic (Beck, 1988; Clark, 1986a, 1986b, 1988, 1996, 1997; Salkovskis, 1988a; Salkovskis & Clark, 1986) has been developed, based on initial work by Clark (1979) and Beck, Emery, and Greenberg (1985). This fundamentally simple hypothesis states that patients with recurring panic attacks have an *enduring tendency* to misinterpret certain bodily sensations as a sign of imminent disaster. The way in which this accounts for acute panic attacks is summarized in Figure 1.

According to the hypothesis, acute panic results from the misinterpretation of bodily or mental sensations as signs of imminent personal disaster. The anxiety engendered by the misinterpretation of sensations produces an increase in sensations, which can in turn feed back to the misinterpretation, rapidly culminating in a full-blown panic attack. Thus, according to the cognitive hypothesis, panic occurs only if sensations are misinterpreted; patients who experience repeated panic attacks are particularly vulnerable to making such misinterpretations by virtue of a pre-existing set of beliefs. A variety of things may trigger off the panic vicious circle in the first instance; it may be triggered by anxiety from general stress, by the anxiety of entering a situation where panic previously occurred, by a sensation from an unrelated source such as a hangover or too much coffee, by a frightening thought, and so on. It is important to note that the whole process of panic generation can occur within a few seconds, as the person responds physiologically and psychologically to what seems, at that time, to be a profound threat to his or her safety.

For example, a patient may interpret palpitations and a racing heart as a sign that he is having a heart attack. This misinterpretation in turn results in intense anxiety and thus increases the sensations associated with autonomic/physiological arousal, including palpitations, tachycardia, dizziness, and precordial pain. This increase in intensity and range of symptoms appeared to confirm the original misinterpretation, further increasing anxiety and symptoms and so on, rapidly culminating in an acute panic attack.

A wide range of symptoms can give rise to misinterpretations, but the cognitive hypothesis proposes that those involved in panic attacks are particularly likely to be sensations which can result from autonomic or central nervous system responses to anxiety itself, given the immediate nature of the feedback loop. A further factor in the readiness to misinterpret bodily sensations should be the extent to which the person has available any innocuous alternative explanations of the intense and wide-ranging sensations associated with panic attacks. For example, if someone were to notice their heart racing, being short of breath, feeling dizzy, and found they were sweating a great deal immediately after running to catch a train, misinterpretation is unlikely. The same sensations experienced without any obvious cause would, at best, be bewildering and at worst be taken as a sign of serious illness.

The catastrophic beliefs specified by the cognitive hypothesis account for the intensity of anxiety and the associated physical symptoms, insofar as the anxiety reaction experienced would not be considered abnormal if occurring

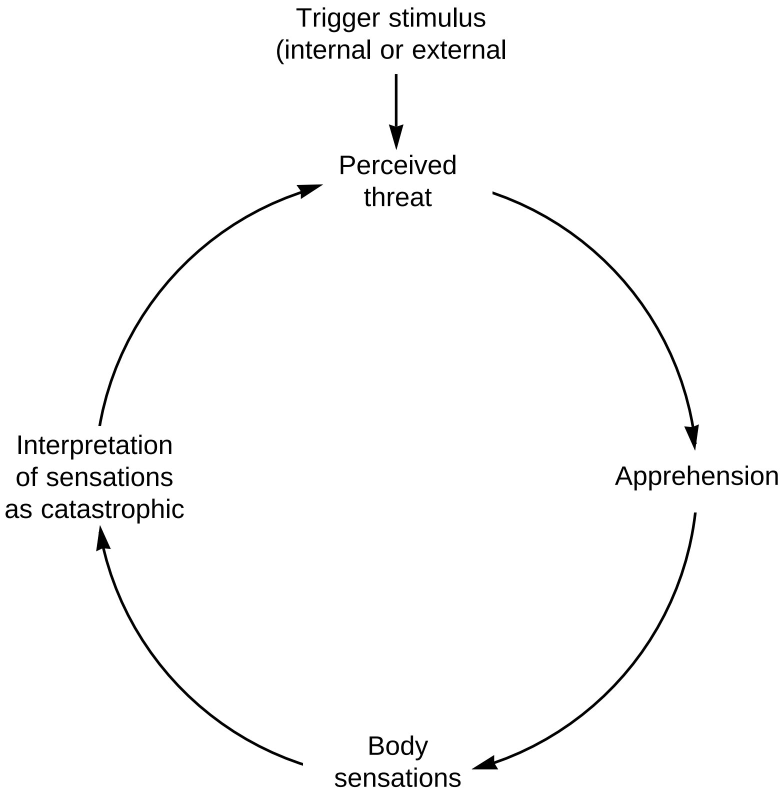

Figure 1 The suggested sequence of events in a panic attack. (Reprinted with permission from Clark, 1986, p. 463).

in the context of a truly life-threatening situation. Typically, patients express very strong beliefs in the possibility of feared disaster during the attacks themselves, although in the clinician's office (when the symptoms are not present and a trusted individual is) patients will report that they do not, at that time, feel convinced that the disasters would happen. The apparent unexpectedness or "spontaneousness" of some panic attacks can also be accounted for; although the panic may start with a mild (and often normal) physical sensation, if such a sensation triggers off the thoughts of disaster and hence a panic, the originating sensation may then be lost in the surge of much more intense, anxiety-generated symptoms which follow. Often, there is no specific explanation for the triggering symptom; it was simply one of the many ordinary physical fluctuations which most people experience every day.

6.18.5.3 The Importance of the Idiosyncratic Nature of Catastrophic Misinterpretations

The misinterpretations made by individual patients are based on aspects of their experience, such as the person's previous experience (direct or vicarious) of symptoms and their meaning. For each patient, there tends to be an internally consistent and logical link between the sensations experienced during panic and the particular interpretations made. Some of the most commonly occurring sensations and related interpretations are shown in Table 2.

The link between particular sensations and interpretations are frequently based on conventional wisdom and "common sense" so that the links are immediately obvious (e.g., shortness of breath interpreted as a sign that the patient is about to stop breathing), although the links may not always be so clear to the observer unaware of the patient's specific pattern of beliefs.

Although it has not as yet been established why some people begin to misinterpret bodily sensations in the first place, there are two main possibilities (which may operate in separate ways or, more likely, in combination). Some individuals may be in a transiently vulnerable state because of biochemical factors (e.g., drugs, hormonal disturbances, etc.; see Roy-Byrne & Uhde, 1988) or recent stressful life events (Finlay-Jones & Brown, 1981, Pollard, Pollard, & Corn, 1989), particularly when those events

Table 2 Examples of the association between symptoms and catastrophic misinterpretations occurring during panic attacks.

Sensation	*Typical misinterpretations*
Heart racing, pounding, palpitations	I'm having a heart attack, my heart will stop, I'm dying
Breathlessness	I'm going to stop breathing, suffocate
Feeling unreal and distant	I'm going to go crazy, lose my mind
Loss of sensation and tingling in arms and legs	I'm having a stroke
Feeling dizzy, faint, weak legs	I'm going to faint, fall over, pass out
Feeling distant, tense, sweaty, and confused	I'm about to lose control of my behavior
Feeling dizzy, heart pounding, chest tight, palpitations, flushed, tingling	I'm dying

concern serious illness in the patient him- or herself or in friends or relatives. Critical incidents of an apparently less serious type may serve the same triggering function (e.g., hearing of a similarly aged colleague at work who had a heart attack). Under such circumstances, patients may more readily misinterpret bodily sensations as harmful when they are unable to generate any convincing innocuous explanation. Second, particular attitudes and assumptions may predispose patients to the misinterpretation of particular circumstances, especially those concerning the effects of anxiety. An individual who held the belief that anxiety can kill may become alarmed as they go through a period of intense anxiety (due, for example, to excessive job stress or illness) at a level which they had not previously experienced. A substantial subgroup of such attitudes have been subsumed under the heading of "Anxiety sensitivity" (Reiss, Peterson, Gursky, & McNally, 1986), which has previously been shown to be high in panic patients (e.g., McNally & Lorenz, 1987) and nonclinical panickers (Donnell & McNally, 1990) and to predict the response of nonclinical subjects to panic-related tasks such as hyperventilation (Holloway & McNally, 1987).

6.18.5.3.1 Panic, cognitions, and avoidance

A variety of researchers have attempted to conceptualize the relationship between panic and avoidance. Rachman has carried out an influential series of experiments in which he examines the relationship between predicted fear and actual fear in subjects repeatedly confronting aversive events (summarized in Rachman & Bichard, 1988). The basic paradigm used involved asking student volunteers, previously identified as claustrophobic, to repeatedly enter a very small enclosed space; in the course of experimental sessions they are asked to rate anxiety and a range of other variables, particularly their expectation of anxiety prior to entering the enclosed space. Using this paradigm, it was found that anxious subjects were consistently more likely to overpredict than underpredict the fear associated with phobic situations, and overpredictions were particularly likely to follow underpredictions. Reductions in fear were most likely after overpredictions, but there was evidence of an inherent bias towards overprediction of aversive events, including both anxiety provocation and pain (Rachman & Bichard, 1988). Rachman (1990, chap. 17) proposes that if agoraphobics show the same type of tendency as people with other types of fear to overpredict, then avoidance behavior may be a product of overprediction. Rachman goes on to suggest that, in agoraphobia as in claustrophobia, the occurrence and intensity of panic attacks will form the basis of predictions of fear. He also suggests that the anticipation of fear may itself provoke situational panic attacks, and that the occurrence of such panic in turn affects subsequent avoidance. Although this view is consistent with clinical observations of agoraphobics' pessimism regarding the impact of exposure despite repeated positive experiences of anxiety reduction (and reluctance to continue or repeat exposure sessions), more direct evaluation is required if overpredictions are to be regarded as a key factor in the maintenance of avoidance behavior (Rachman, 1990).

Other direct attempts to conceptualize and predict the relationship between avoidance related to naturally occurring panic outside the laboratory setting, or as a factor related to individual differences in anxiety responding among panic patients, have met with less success. A range of factors are weak predictors of avoidance behavior (Craske, Rapee, & Barlow, 1988; Mavissakalian, 1988; Warren, Zgourides, & Jones, 1989). Craske and Barlow (1988) review the data, and summarize the range of factors which have been found to relate to avoidance. They note that most important identified to date are expectancy of anxiety, the extent to which patients have a predominantly somatic focus of anxiety, the extent to which patients perceive panic to be related to negative consequences beyond anxiety itself (as in anxiety sensitivity), and access to safety signals. They attempt to synthesize this work within the context of Barlow's biobehavioral hypothesis. However, Craske and Barlow's discussion has a major limitation in the present context, because the approach applies only to situational and expected panic attacks. The importance of spontaneous and/or unexpected panic attacks in the origin and maintenance of avoidance is stressed by most theories including Barlow's own; Craske and Barlow propose no specific basis for this in their discussion, presumably because they assume that spontaneous panic attacks are biologically determined.

The cognitive hypothesis specifies that situations which generate anxiety might become the focus of avoidance, but this will only become debilitating when accompanied by fears that the anxiety might lead to other, more serious consequences. Furthermore, the scope of avoidance could be regarded as broader than generally encompassed by behavioral descriptions (e.g., Marks, 1987b), with both subtle and more generalized avoidance playing a major role in the maintenance of panic attacks (Salkovskis, 1988a). For example, a patient who interprets weak legs as a sign that he may collapse attempts to prevent collapse by holding on to nearby objects, tensing his legs and seeking a seat at the earliest possible opportunity. By doing so, he has a further effect; he prevents disconfirmation of his fears of collapse. The patient is unaware of the anxiety maintaining effects of his avoidant behavior (described here as "safety seeking" behavior). The effect of his behavior on his perception of what happened is to transform an incident which could have provided a disconfirmation of his fears into evidence bolstering his negative interpretation of symptoms, in the form that he has just experienced a "near miss." The situation would be interpreted as "If I had not prevented it by tensing my legs, then I would certainly have collapsed." The cognitive hypothesis predicts an internally logical match between such beliefs and behaviors during panic; for example, fears of loss of control should be associated with attempts to control oneself. Similar considerations can be applied to more generalized forms of actual avoidance and escape behavior; an agoraphobic who decides not to go shopping on a particular day may conclude "It's lucky I did not go, otherwise I would have had an enormous panic; if I had panicked today, I would certainly have collapsed." Once again, avoidance has "prevented" collapse. However, these types of behaviors involving rapid "escape" from the immediate situation are only logically possible when the feared catastrophe has external correlates; that is, simply leaving a situation has little value as a strategy for dealing with an impending heart attack. The main "usefulness" of such an escape strategy would be in situations where social evaluative concerns predominate; removing oneself from a place where there are other people is likely to be perceived as helpful both as direct catastrophe avoidance and as a means of removing the person from the scrutiny of others.

As panic and avoidance become more chronic, the behaviors involved probably become habitual and awareness of the specific cognitive component of avoidance will tend to diminish except when directly provoked by deliberate of accidental exposure. Often patients express this as the desire to escape; for example, when asked what went through his mind in a phobic situation, patients typically respond "I just had to get out." The cognition motivating this wish to escape is readily revealed by asking what, at that time, would he have thought the worst thing that could have happened should he have been unable to get out. Thus, the cognitive analysis of avoidance involves an analysis of what the patient is avoiding rather than just of the anxiety arousal/relief associated with the specific situation. The importance of the minutiae of anxiety related and safety seeking behavior also takes on a new importance, particularly for therapy.

The cognitive hypothesis proposes a specific set of links, both between panic and avoidance and vice versa. If panic patients fear imminent disasters because of their misinterpretation of bodily sensations, it follows that their behavior should be logically related to the avoidance of the feared catastrophes rather than of anxiety *per se*. This means that avoidance behavior would be meaningful but idiosyncratic both to the individual and to attacks involving specific types of misinterpretations and the individual experiencing them.

Support for this view comes from a study by Salkovskis, Clark, and Gelder (1996). In a preliminary investigation of this hypothesis, data were collected from a questionnaire devised as an assessment of safety seeking behaviors in panic together with assessments of some of the more common panic-related cognitions in a sample of 147 panic patients. The pattern of associations was consistent with predictions from the safety seeking perspective. Holding on to an object was associated with fears of fainting and being paralyzed with fear. Holding on to or leaning on another person was associated with fear of fainting. Sitting down was associated with fear of heart attack, acting foolishly, and being paralyzed with fear. As expected, keeping still was exclusively associated with fear of having a heart attack. Doing more exercise was only associated with being paralyzed with fear. Focusing attention on one's body was associated with thoughts of having a tumor, choking to death, and having a stroke. The specific association with controlling one's behavior were with thoughts of acting foolishly and not being able to control oneself. These cognitions were also associated with trying to move more slowly, reflecting the attempt to exercise control over one's behavior. The beliefs associated with looking for an escape route are exclusively with loss of control type concerns (acting foolish, losing control, and being paralyzed with fear), and not with thoughts concerning the more somatically-focused catastrophes. This finding was expected; leaving a situation is a relatively ineffective remedy for internally located problems, where the catastrophe would be carried with the patient out of the situation. By contrast, the negative consequences of loss of control type events are almost exclusively social evaluative. Asking people around for help was associated with thoughts of having a heart attack and choking to death, both likely to be perceived as extremely serious and uncontrollable somatic catastrophes, likely to require immediate external aid. The pattern of associations between specific behaviors and cognitions found was therefore consistent with the hypothesis that cognitions may "drive" the anxiety related behaviors in a meaningful and idiosyncratic way. Particular avoidant behaviors may be occurring because they are intended by the patients as logical reactions designed to avert feared catastrophes. These findings are consistent with the cognitive hypothesis as a "normalizing" account of panic and associated phenomena (particularly avoidant behaviors), highlighting the internal logic of the problem.

6.18.5.4 Agoraphobia

Within the cognitive framework, agoraphobia is therefore regarded as motivated avoidance. In agoraphobia, the avoidance is of situations which involve being away from safety, most commonly embodied by the person's home (or other trusted helper's homes) and its extension by other "safe" objects (e.g., the person's car). This does not necessarily mean that the person is free of anxiety when at home, but that they feel relatively safer there than in other situations. The fear in agoraphobic situations revolves around not being able to leave the situation for a safer one (or not being able to do so without embarrassment). This distinguishes agoraphobia from problems in which other types of phobic avoidance predominate because the person does not exclusively avoid (or endure with considerable anxiety) situations where they are likely to be negatively evaluated (as in social phobia) or be in a confined space (as in claustrophobia) or avoid because of some other type of anxiety (such as obsessive-compulsive disorder or post-traumatic stress disorder). However, fear of these other types of situations may be present in many people suffering from agoraphobia, as is it perfectly possible to experience multiple fears of this type.

Such a view has the merit of considering agoraphobic avoidance as a distinct psychological phenomenon (with much in common with other types of avoidance) rather than as a symptom of some other diagnosis. According to this view, people develop a pattern of avoidance of particular situations because these situations have become associated with unpleasant experiences (or the expectation of unpleasant experiences). These associations may be historical (and may therefore be relatively inaccessible to introspection), or may be more recent and vivid. This helps make sense of why panic attacks are neither necessary nor sufficient for the experience of agoraphobia, but why there is such a strong association. Other types of anticipated unpleasant experience which can lead to an agoraphobic pattern of behavior include epileptic attacks, incontinence, and irritable bowel (i.e., episodes where the person believes they are in danger of losing control over their bowels). Agoraphobia can develop in the elderly who fear falling and breaking their bones. This way of viewing agoraphobic avoidance has the further advantage of normalizing the behavior. Avoidance as a reaction to the perceived possibility of physical or social threat is, of course, an understandable reaction.

Within this framework, panic is the single most common factor associated with agoraphobia. This then raises the important question of why only some people develop agoraphobia when they experience panic attacks. (The same question clearly applies to irritable bowel problems, epilepsy, and other associated features; for understandable reasons research has tended to focus on the association with panic.) The second and more difficult question concerns those people who have no panic or "panic like symptoms" associated with their agoraphobia. There are several ways in which a tendency to avoid particular situations may result in actual avoidance behavior. The person may be particularly strongly motivated because their fear of agoraphobic situations is especially intense (as is usually the case when panic is present or anticipated) or they may believe they are particularly vulnerable to even relatively small amounts of fear, perhaps because they underestimate their ability to cope either with the agoraphobic situation or their own emotional reactions. Before a more detailed analysis of theories of agoraphobia, clinical factors thought to be meaningfully correlated with agoraphobia will be considered.

6.18.5.4.1 Correlates of agoraphobia

One view about agoraphobics which has been fairly prevalent is that they may show two basic dispositional qualities: dependence on others, and a tendency to cope with difficulties by using avoidance as a coping method (e.g., Andrews, 1966; McGennis, Nolan, & Hartman, 1977; Shafer, 1976). Andrews also suggests that this may be due to maternal overprotection. Mathews et al. (1981) attempted to survey the evidence which could be brought to bear with regard to this theory. The seven studies reviewed present somewhat equivocal results, although several did find evidence of overprotection, dependency, and somewhat unstable and more "anomalous" families (with more adopted children, etc.). Mathews et al. conclude that few properly conducted studies have been done, but that there is some suggestive evidence of dependence as a pre-existing trait. Reich, Noyes, and Troughton 1987) compared subjects who had panic disorder with varying amounts of agoraphobic avoidance, and found that about 40% of subjects with some (as opposed to no) phobic avoidance met criteria for dependent personality disorder, although it was not possible to determine whether the dependent behavior was primary or secondary to the agoraphobia. Kleiner and Marshall (1987) reported a high degree of dependent behavior in agoraphobics, prior to the onset of the phobia, and Borden and Geller (1981) in their review suggested that dependent personality traits are a key feature of agoraphobia.

There is some evidence that people who go on to develop agoraphobia may have been more fearful of being out and about in the world premorbidly. A history of school phobia is more common in agoraphobics than in panic patients, and the relatives of agoraphobics are more likely to suffer from school phobia or agoraphobia (Deltito, Perugi, Maremman, Mignani, & Cassano, 1986; Gittelman-Klein & Klein, 1984). There is also evidence of behavioral inhibition (defined as a tendency to have a constricted range of exploratory behavior) in agoraphobics premorbidly (e.g., see Rosenbaum et al., 1988). Renneberg, Chambless, and Gracely (1992) studied the incidence of *DSM-III-R* Axis II personality disorders in a large group of agoraphobics, and found that 56% of the sample had at least one personality disorder, of which avoidant personality was the single most frequent disorder. They also note that personality disorders seem more common in agoraphobics than in individuals with panic disorder (see also Friedman, Shear, & Frances, 1987, and Green & Curtis, 1988)

Chambless and Goldstein (1982) report that agoraphobic patients show low scores on the Bernreuter Inventory of self-sufficiency (although they also note that it incorporates items to do with activities to be done alone). Buglass, Clarke, Henderson, Kreitman, and Fredey (1977) reported no extra premorbid dependency in agoraphobics than in a matched group of normals, but found more conflict over dependency on the mother in the agoraphobic group. They may have contaminated their results by excluding those agoraphobics with marked dependency. Torgesen (1979) studied a small group of monozygotic twins of patients with agoraphobia. He found that the agoraphobic twin was more likely to have been dependent, self-doubting, and suggestible on a personality inventory, and to report having been like that since childhood. They were also likely to have been the second twin, and the smaller one. Chambless and Goldstein (1982) report two other studies on assertiveness in agoraphobics. In one they found that the agoraphobics were less assertive than simple phobics on therapist ratings, and in the other they found that they were less assertive on assertion inventories at intake than a group of college students, and more anxious about assertion. Rapee and Murrell (1988) also found that very avoidant individuals scored higher on the Eysenck Personality Questionnaire and lower on a measure of assertiveness than minimally avoidant subjects.

Most studies report a higher percentage of women in groups of agoraphobic patients than in groups with panic disorder without avoidance (Chambless, 1985; Wittchen, 1988), this has led to the stereotyped notion of the typical agoraphobic as a housebound housewife. Chambless (1985) does, however, point out that of her sample of 378 agoraphobics, 64 were men and only 52% were currently married, so that this description fitted less than half of the patients. There has, however, been considerable interest in the relationship between gender and avoidance in patients with agoraphobia. There has been speculation that, where the roles adopted are more "traditional," it is easier and more acceptable for women to become housebound than men, and for men to use alcohol as an alternative coping strategy. The stereotypical female gender role is also associated with traits of dependency and unassertiveness, both found to be prominent in agoraphobics. This literature is reviewed in detail by Chambless (1985).

A number of studies indicate that greater degrees of depression are associated with more severe avoidance in agoraphobia (Sanderson & Barlow, 1986; Klosko, Shadick, Heimberg, & Barlow, 1986; Telch et al., 1989; Vitaliano et al., 1987). This finding was not replicated in several other studies (e.g., Rapee & Murrell, 1988; Thyer, Himte, Curtis, Cameron, & Neese, 1985). Aronson and Logue (1987) reported a reliable difference between PD and PDA such that depression was more likely in individuals who later developed avoidance, and McNally and Lorenz (1987) found that in a group of PDA patients depression predicted a resurgence of avoidance. The association between depression and avoidance may be conceptualized within the theoretical framework of learned helplessness and attributional style, if it is found that PD patients with avoidance have weaker beliefs in their own ability to cope with stress. Klosko et al. (1986), who showed that panic disorder patients with avoidance were more likely to attribute negative events to stable and global factors, and Telch et al. (1989) showed that panic disorder patients with avoidance were likely to rate their ability to cope with panic as lower than patients with panic disorder without avoidance.

Several studies indicate that there is very little difference between the thoughts of possible physical consequences of bodily sensations (or in the extent to which they fear them) in people suffering from panic with agoraphobia as opposed to panic patients with minimal avoidance. The main difference observed is a greater fear of dizziness, and a higher frequency and belief in thoughts of fainting among the agoraphobics (Salkovskis, 1990; Telch et al., 1989). In the study by Telch et al., the more avoidant group showed much higher scores on scales reflecting fears of loss of mental control, or social ridicule. These results echo those of other studies which have found that agoraphobics tend to have more social evaluative concerns than patients with panic disorder (de Ruiter & Garssen, 1989). In the study by Telch et al., agoraphobics were found to have less perceived self-efficacy relating to dealing with panic than other panic patients. Hoffart (1995) has also shown that low scores on a measure of perceived self-efficacy predict situational avoidance more strongly than other measures, including a measure of catastrophic beliefs about the symptoms of panic.

6.18.5.5 The Cognitive Account and Research into Panic

Before examining previous work specifically designed to evaluate predictions derived from the cognitive hypothesis, it is first important to consider how one of the key observations thought to support a more biological view is encompassed. The provocation of panic by challenge tests such as lactate infusion and carbon dioxide inhalation has been described as a "biological marker" for panic, in that such provocations do not have the same effect on nonpanic control subjects. Clark (1986a,1986b, 1988) suggests that the research into "biological" panic provocation potentially represents some of the strongest support for the cognitive hypothesis. As noted above, a wide range of procedures provoke panic attacks in Panic Disorder patients but not in control subjects, although the procedures concerned have no identifiable common biochemical or physiological basis, making it difficult to envisage any specific biological mechanism. They do, however, have a common psychophysiological feature relevant to the cognitive hypothesis, which is that all of these substances induce a range of intense physical sensations in all subjects, panic or otherwise. Thus, the tendency to panic under such diverse provocations is consistent with the hypothesis that panic arises from the misinterpretation of bodily sensations. For example, it may be that panic patients interpret the effects of panic-inducing procedures as a sign of some kind of adverse reaction in their body to the inductions, all of which involve some kind of unusual physical procedure. To test this possibility, a number of researchers have carried out experiments into psychological factors affecting biological inductions.

In a particularly elegant experiment, Sanderson, Rapee, and Barlow (1989) demonstrated that the effects of carbon dioxide inhalation are modified if panic patients believe that they can control the inhalation by switching it off. In the experiment, the button which was supposed to turn off the carbon dioxide was not, in fact, connected, so the fact that only two patients out of the 10 in the perceived control condition panicked as compared to eight of 10 patients in the comparison group is attributable to the illusion of control. In an experiment in which hyperventilation was used as a provocation, the effect of hyperventilation was compared in panic patients and patients having a diagnosis as general anxiety disorder (Rapee, 1986). In this study, panic patients recognized the effects of hyperventilation as very similar to their experience during panic attacks, while patients suffering from generalized anxiety disorder did not. However, none of the 20 panic patients actually experienced a full attack, and the degree of similarity between hyperventilation and panic was highly variable. This result can be readily accounted for by the cognitive hypothesis, because in this experiment the patients will have a clear explanation of why symptoms are occurring, so that they are unlikely to misinterpret their sensations catastrophically, particularly as the provoking "agent" is a readily controllable behavior (breathing quickly and deeply). The absence of anxiety-provoking thoughts noted during the experiment would also have had the effect of minimizing the autonomic arousal which normally occurs at the same time as symptoms of hyperventilation during normally occurring panic, reducing the perception of similarity.

Another experiment from the same laboratory (Rapee, Mattick, & Murrel, 1986) manipulated cognitive factors prior to 50% CO_2/50% O_2 inhalations, a procedure which has been shown to induce panic attacks in panic patients but not in normal controls. In this experiment, subjects were either given a full account of the effects of the inhalation or given only minimal instructions. Panic patients who were not given the full explanation perceived the effects of the inhalation as more similar to panic and experienced more catastrophic cognitions than patients who were given an account of the effects. Groups of social phobics compared on the same basis showed no effect of instructions, demonstrating the specificity of this finding to panic patients as opposed to other anxious patients.

Recently, an experiment has been carried out with the most important of these substances, sodium lactate; Clark et al. (in preparation) demonstrated that, if patients are given detailed information which prevents misinterpretation of the symptoms of the infusion, panic is blocked. Thus, the cognitive hypothesis provides a testable account of the effects of so-called biological panic provocation tests, and this account has already received some support from experimental investigations of the mechanisms involved.

6.18.5.6 The Relevance of Psychobiological Factors to the Cognitive Hypothesis of Panic

The cognitive model does not rule out the possibility that some Panic Disorder patients may be physiologically more vulnerable to episodes of panic, for instance because of biological differences in autonomic lability associated with an increased perception of bodily or "mental" sensations. For example, it seems likely that there may be a genetic component to emotionality, which may make particular individuals prone to experiencing relatively intense reactions to threat. Indeed, such an observation would be quite consistent with the cognitive hypothesis. For example, if there was an identifiable subgroup of subjects who were particularly likely to experience intense and apparently inexplicable physiological sensations, it is quite likely that such subjects would be predisposed to panic. However, without the element of catastrophic misinterpretations, such individual differences would be insufficient to account for panic attacks. Indeed, many people actively seek out circumstances in which they are likely to experience heightened levels of arousal (e.g., horror films, exciting sports). This point is illustrated by the example of hyperventilation, which presents some problems of classification briefly discussed above, where it was concluded that although hyperventilation was neither necessary nor sufficient to account for panic, the data concerning the relationship between hyperventilation and panic strongly suggested some kind of link.

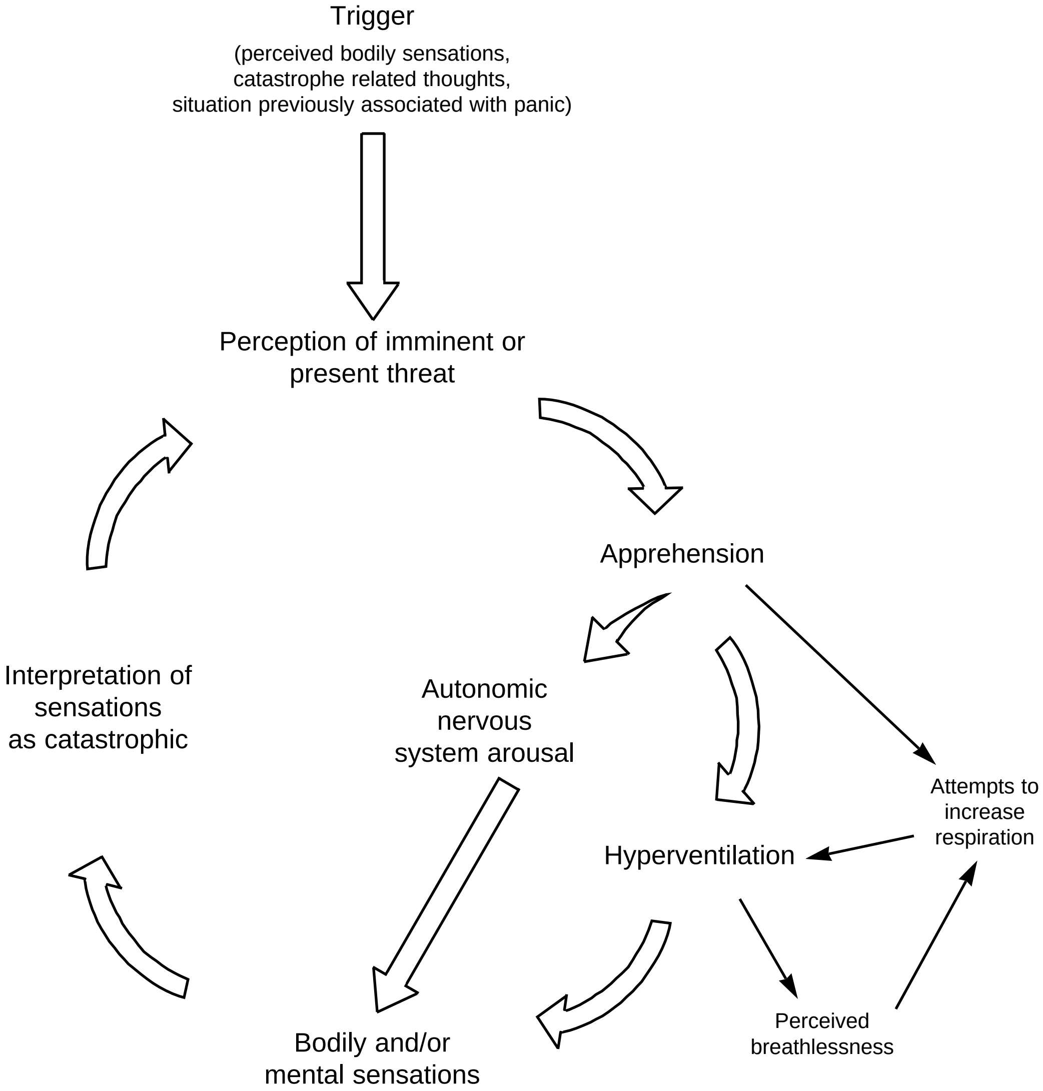
6.18.5.6.1 The cognitive link between panic and hyperventilation-induced symptoms

As described above there are a range of findings which strongly suggest that hyperventilation may be involved in some way in panic attacks. However, the hyperventilation hypothesis of Ley and others is not well supported by the experimental evidence. The association between panic and hyperventilation can best be accounted for by the cognitive hypothesis of panic, the early development of which was intimately connected with interest in the role of hyperventilation in the physical symptoms experienced by some patients (Clark & Helmsley, 1982; Salkovskis, 1988a, 1988b).

The way in which the cognitive hypothesis can account for the apparently conflicting data concerning the link between panic and hyperventilation is illustrated in Figure 2, which is a specific development of Figure 1. Although in his schema for the link between hyperventilation and panic, triggering sensations may sometimes arise from hyperventilation, this is not in any sense required in the way demanded by Ley (1985a, 1985b) (cf. Hibbert & Pilsbury, 1989). Upsetting thoughts, images, and situations which have previously been associated with panic are probably more likely to serve as triggers (Clark, 1988). The perception of threat results in apprehension, which in turn results in arousal and, in some instances, hyperventilation. If (and only if) the bodily sensations which then occur are interpreted as a sign of imminent personal harm of internal origin, then anxiety and bodily sensations are likely to show a further and sudden increase which will in turn be catastrophically misinterpreted, and so on round in a vicious circle culminating in a panic attack.

There are several additional points which emerge from this analysis. It is proposed that stress induced hyperventilation can be a source of intense and frightening bodily sensations, although such sensations are not intrinsically either unpleasant or frightening (Clark & Helmsley, 1982). Thus, hyperventilation can be an effect of anxiety and stress; if and only if the sensations are misinterpreted in a catastrophic fashion, then hyperventilation-induced sensations can then also become a "cause" of stress as part of the cognitive mechanism described above (Salkovskis & Clark, 1986). Increases in respiration are a normal part of the stress response and can occur without awareness, probably making misattribution more likely in vulnerable individuals.

Even in instances where hyperventilation does occur during a panic attack, note that the anxiety arising from the catastrophic misinterpretation of hyperventilation-induced bodily sensations is very likely to be accompanied by autonomic arousal in addition to the effects of hyperventilation. This means that, even in panic attacks in which hyperventilation



Trigger
(perceived bodily sensations,
catastrophe related thoughts,
situation previously associated with panic)
Perception of imminent or
present threat
Apprehension
Interpretation of
sensations
as catastrophic
Autonomic
nervous
system arousal
Attempts to
increase
respiration
Hyperventilation
Perceived
breathlessness
Bodily and/or
mental sensations

Figure 2 The principal components of the cognitive model applying to panic attacks in which hyperventilation is involved in the production of symptoms.

is involved, many of the sensations which occur may not be due to the effects of the respiratory alkalosis alone, making the importance of the effects of hyperventilation more difficult to determine.

There are several reasons why hyperventilation is a particularly powerful mechanism for the production of sensations which are subsequently misinterpreted. Hyperventilation can produce a wide range of sensations very quickly. Some of the sensations produced by hyperventilation are often unfamiliar even to patients who have previously experienced intense anxiety in specific situations (e.g., parasthesias, dyspnea, tetany), as is the sudden onset and rapid increase of symptoms. When dyspnea is associated with panic, as is often the case (Pollard, 1986), this may be misinterpreted as a sign that breathing is about to stop. This specific misinterpretation increases the likelihood that patients will respond to sensations by a deliberate increase in their breathing (Bass & Gardener, 1985), which will in turn have the effect of further intensifying sensations. Patients often report taking "deep breaths" in an attempt to calm themselves down when anxious. Such behavior is particularly associated with misinterpretation of breathlessness as a sign of imminent cessation of breathing. This means that, for some patients, panic associated hyperventilation might be entirely determined by voluntary effort directed at the prevention of suffocation.

Finally, there is evidence that repeated episodes of hyperventilation over a longer period can result in a change in the buffer set point as renal excretion of bicarbonate compensates for respiratory alkalosis of longer durations, as happens in altitude adaptation (Okel & Hurst, 1961). This adaptation has the effect of lowering resting p_aCO_2 levels and increasing the sensitivity of the buffer system to challenge. That is, low resting p_aCO_2 does not itself produce symptoms, but small changes in CO_2 (such as are associated with exercise or mild stress) produce relatively greater increases in respiration. This phenomenon will also have cognitive effects, as patients notice their increased sensitivity, and interpret this as further evidence for their belief that panic attacks are signs of a serious illness or harm. Although several studies have demonstrated that the resting p_aCO_2 levels of panic patients are significantly lower than those of normal controls, the only well-conducted study to examine the study of central CO_2 regulation failed to find any evidence of increased sensitivity (Woods et al., 1986). (This negative finding might be accounted for by the fact that panic patients did not differ from controls in resting level of p_aCO_2.) Thus, it can be concluded that the evidence is consistent with the view that hyperventilation can play an important role in the maintenance of panic in some individuals, but that it is neither necessary or sufficient. The symptoms of hyperventilation will only be involved in the mechanism of panic to the extent that they subject to specific catastrophic misinterpretations.

Consistent with such a cognitive view is the data from a study by Salkovskis and Clark (1990). Neurobiological hypotheses regard localized (brainstem) effects of pH changes (particularly secondary to respiratory alkalosis; Liebowitz et al., 1986) as being the basis of acute panic attacks. Hyperventilation-based theories (Fried, 1987; Ley, 1985a, 1985b; Lum, 1976) also regard the aversive effects of respiratory alkalosis to be central to the experience of panic. In both instances, hyperventilation is regarded as a biologically-based panic induction procedure. On the other hand, the cognitive hypothesis specifies that hyperventilation is not intrinsically aversive, and that the affect experienced will be a function of the way symptoms are interpreted. If this is so, this would also be further evidence that hyperventilation is neither necessary nor sufficient for the experience of panic, and highlights the intrinsic weakness of unmodified breathing control exercises as a means of treating panic. Salkovskis and Clark (1990) experimentally manipulated the way in which symptoms of hyperventilation were interpreted. Nonclinical subjects were provided with a relatively positive or relatively negative interpretation of the effects of hyperventilation, and the results evaluated both in terms of subjective and physiological responses. Those given a positive interpretation responded to the sensations as pleasant, while those given a negative interpretation found them aversive. Furthermore, affect was strongly correlated with the intensity of bodily sensations experienced, but only the affect congruent with the interpretation given.

6.18.6 EVALUATING THE COGNITIVE HYPOTHESIS

Clark et al. (1988) enumerated predictions directly arising from the cognitive hypothesis of panic disorder. Experimental studies have evaluated the cognitive account of laboratory-based biochemical panic inductions (Clark, 1993) and the presence of catastrophic misinterpretations of bodily sensations, both as an enduring characteristic of patients suffering from Panic Disorder and as a more acute phenomenon occurring during panic attacks themselves (reviewed in Salkovskis, 1989).

Chambless and Gracely (1989) evaluated the cognitions of patients with diagnoses of Panic Disorder, Agoraphobia with Panic, Generalized Anxiety Disorder, Social Phobia, Obsessive-Compulsive Disorder, and Depression. They found that Agoraphobics scored higher than all other groups on fear of physical sensations; both Agoraphobics and Panic Disorder patients scored higher than all other groups on thoughts that physical harm would result from their anxiety. They also found that, in Agoraphobics, fear of bodily sensations and agoraphobic thoughts (i.e, catastrophic cognitions) predicted self-reported avoidance behavior even when the effects of trait anxiety were statistically removed. Similar results were found by Hout van den, van der Molen, Griez, and Lousberg (1987) for fear of bodily sensations in Panic Disorder patients, who were significantly different from nonpanic "neurotic" patients and normal controls.

Rachman and Levitt (1985) tested claustrophobic subjects, who were asked to enter a very small confined space (a "closet"). They demonstrated that, in subjects experiencing a panic attack in this situation, breathlessness was particularly associated with thoughts of suffocation. Furthermore, they found an association between failure to habituate to repeated exposure and the specific presence of thoughts of suffocation, as they had predicted from a cognitive analysis based on the misinterpretation hypothesis.

McNally and Foa (1987) and Dattilio and Foa (1987) (described in Foa, 1988) used variants of questionnaires employed by Butler and Mathews (1983). The questionnaires were intended to tap two main phenomena:

(i) The subjective probability and perceived aversiveness of bodily sensations, in which subjects rate the likelihood of occurrence of interoceptive sensations and externally-based fear situations, together with judgments of how aversive such occurrences would be. Although the results show elevated subjective probabilities and cost in panic groups compared to anxious controls for interoceptive stimuli and not external fear situations, the results for this questionnaire are difficult to interpret because the *actual* probabilities for the experience of interoceptive (i.e., panic) symptoms are, by definition, likely to be considerably higher for the panic patients.

(ii) The interpretations which might be made of vignettes concerning interoceptive or external stimuli (McNally & Foa, 1987). This questionnaire provides the subject with a range of imaginary scenarios and asks the subject what they think is happening in the specified situation. Subjects respond by endorsing one of three options, which include two neutral interpretations and one negative or catastrophic option. For example, an item might be

> You notice your heart is beating quickly and pounding.
> Why?

and offer the options:

> Because you have been exercising
> Because there is something wrong with your heart
> Because you are excited

Panic patients were found to score higher than controls not only on internal (body sensation) items, but also on external threat situations. However, direct examination of Foa's version of the questionnaire reveals a specific problem, which is that there is confusion between negative interpretations *per se* and panic-related responses. Thus, many of the "negative" choices offered are "Because you are about to panic" or "Because you are very anxious." In the same paper, Foa presents laboratory data from an otherwise unpublished experiment by Mansueto, Grayson, and Foa on the subjective and physiological responses to imagery of internal and external fear stimuli. The results show that agoraphobic patients show significantly elevated subjective anxiety and heart rate responses to imagery of external fear situations, imagery of autonomic fear responses alone, and the two combined compared with neutral imagery. Specific phobics showed a similar pattern, except that imagery of autonomic fear responses alone was not different from neutral imagery. However, the analysis presented is solely within-group; Foa does not specify whether the groups differed on this item (i.e., whether there was a significant group X condition interaction). Inspection of means provided suggests that there may not have been.

In a study based on the McNally and Foa (1987) experiment described above, but designed more specifically to evaluate the cognitive hypothesis, Clark et al. (1997) used a further variant of the Butler and Mathews (1983) questionnaire in order to evaluate the tendency to misinterpret bodily sensations. This study found that panic patients were significantly more likely to misinterpret physical sensations associated with panic than other anxious patients who did not have panic attacks, but were no more likely than other anxious patients to misinterpret general and social situations.

The results of questionnaire studies of this kind are often criticized because it may be that patients are aware of how they are expected to respond. In a study designed to evaluate the interpretation question without possible subjective biases, a technique called Contextual Priming was used (Clark et al., 1988). This technique, derived from psycholinguistics, is intended to determine subject's expectations of particular meanings as provided by specific contextual cues. An incomplete sentence is projected on a computer screen; for example, "The cat drank the . . .". The sentence fades, and a word replaces it; the person watching simply has to say the word as quickly as possible, and the subject's reaction time is measured using a voice key triggered by the subject's verbal response. Subjects are faster at naming the final word when the word makes a relatively expected completion compared to relatively unexpected completions. In the above example, subjects would be appreciably quicker with the word "milk" than the word "vodka," revealing something about the person's belief about cats' drinking habits. In the experiment with panic patients, the incomplete sentences included items such as "My heart is beating quickly and pounding because I am . . . ". Two possible completions were used for this sentence: "dying" or "excited." Consistent with the cognitive theory, panic patients were significantly faster when catastrophic completions were presented (e.g., the word "dying" in the above example), while controls did not show this difference. This suggests that panic patients have specific negative beliefs, and that such misinterpretations can be rapid and automatic.

Although the demonstration that panic patients specifically misinterpret bodily sensations, it could still be argued that these patients show such misinterpretations because they are experiencing panic attacks rather than vice versa. More convincing and less ambiguous evidence for the theory comes from the prediction that activating misinterpretations should make panic patients (but not anxious controls) experience panic-like states. The task which was devised to do this was a simple word-reading task, where subjects were asked to read words such as

breathlessness-suffocate
palpitations-heart attack
unreality-insane

slowly, as pairs, pausing to dwell on each pair. Seventy-five percent of the panic patients asked to do this experienced a panic attack (as defined by *DSM-III*, viz., experiencing an increase of at least four physical symptoms and a sudden increase in anxiety), as opposed to 17% of anxious controls and no nonclinical controls. Another stressful task (backwards serial sevens) did not differentiate panic patients from anxious controls; although anxiety increased substantially in both groups, none of the subjects experienced a panic attack. Interestingly, no panic attacks occurred when the paired associates task was carried out with a group of panic patients who had been successfully treated by cognitive therapy.

A range of other experimental investigations has now been completed by the Oxford group and others. The cognitive model has been able to explain findings from the biological field (e.g., how biological challenges such sodium lactate provoke panic) and experimentally test these findings (Clark, 1993). On the other hand, biological theorists have been unable to account for findings in the cognitive field. Many specific predictions arising from biological research have been falsified; for example, Gorman et al. (1989) predict that psychological treatments will not reduce anxiety, but will only have effects on avoidance.

6.18.7 TREATMENT

An important clinical prediction from the cognitive hypothesis is that interventions which result in an enduring modification of catastrophic misinterpretations made by panic patients should result in clinically significant improvements in panic. It is important to note that the effectiveness of treatment does not provide any conclusive evidence for the hypothesis upon which it is based. However, ineffectiveness of treatment based on the hypothesis would present considerable problems (Gorman et al., 1989; Teasdale, 1988). Cognitive treatment now emphasizes two major components: (i) strategies designed to help patients to change misinterpretations of bodily sensations as they occur during panic attacks, and (ii) modifying the beliefs upon which such catastrophic misinterpretations are based.

6.18.7.1 The Theoretical Roots of Treatment

Both testable theoretical refinements (such as the importance of safety-seeking behavior as described above) and experimental studies can make contributions to the refinement of treatment techniques and strategies. The way that these examples have had an impact on treatment will be described next.

Some of the most important implications of the cognition-behavior links described above concern treatment (Salkovskis, 1991). In general, cognitive-behavioral treatment emphasizes the need to deal with idiosyncratic factors which bolster the continued misinterpretation of bodily sensations. For example, a patient who became confused during panic describes mentally "holding on to my sanity." In each successive panic he becomes *more* convinced that he would have gone mad were it not for this effort. Another example is the patient who, hundreds of very severe panic attacks later, still believes in each new attack that she is about to go crazy, pass out, or die. Clinically, questioning of such patients reveals that no disconfirmation has occurred because the patients believe that they have, in every instance, been able to take successful preventative action. Thus, each panic is a near miss and further confirmation of the risk. Once such behavioral responses are identified, the patient can be helped to begin the process of reappraisal by withholding such protective responses and learning the true extent of risk. Typically, this may involve suggesting to the patient that they challenge their worries by actively trying to cause the feared disaster, for example, going into the supermarket and trying to faint or try to go mad. This helps the patient to discover that their efforts to prevent these disasters have been misdirected; this can also help the patient to then reinterpret their usually considerable past experiences of such anxiety-provoking situations as true disconfirmations instead of "near misses." This particular type of association might be a fruitful one for investigation, as controlling one's mind is a common response in panic patients as well as other groups, including nonclinical subjects. Given the readiness with which patients can reproduce this type of behavior as either safety-seeking or coping when requested in the laboratory, experiments concerning the use of the same degree of effort directed at different targets (i.e., reduction of anxiety vs. preservation of sanity) could be used to assess the validity of the cognitive basis of such behavior and its putative anxiety-preserving effects when used as a safety-seeking behavior. A further implication is that for the most complete and enduring treatment effects, controlling panic should not be emphasized. Helping people to change their beliefs about the meaning of their symptoms in a more enduring way is the target, and should reduce subsequent vigilance and preoccupation.

The present analysis also suggests ways of combining cognitive procedures and brief exposure in a way which should be particularly effective in bringing about belief change without repeated and prolonged exposure being necessary. Thus, exposure sessions are devised in the manner of behavioral experiments, intended as an information gathering exercise directed towards invalidation of threat-related interpretations. Most previous studies in which cognitive and behavioral treatments have been combined (such as those reviewed in Marks, 1987a, 1987b) have used cognitive procedures as a way of dealing with general and "background" life stresses, most of which tend not to be directly relevant to the specific experience of anxiety. The particular strategy of using exposure as an exercise in testing alternative nonthreatening interpretations of experience would be predicted to succeed better than brief exposure with "supplementary" (threat-irrelevant) cognitive change procedures. That is, such a study should show that "general" cognitive therapy combined with exposure has an additive effect, while "anxiety-focused" cognitive therapy would be expected to multiply the effect of exposure, resulting in maximal cognitive change through behavioral experiments. Thus, according to the cognitive hypothesis, the value of behavioral experiments transcends mere exposure; such experiments allow patient and therapist to collaborate in the gathering of new information assessing the validity of nonthreatening explanations of anxiety and associated symptoms. (Findings consistent with this hypothesis have been found in Social Phobia by Wells, Clark, Salkovskis, Ludgate et al. (1995) and in Panic Disorder with Agoraphobia by Salkovskis et al. (1998).)

Since devising the paired associates task described above as an experimental task for use in the laboratory, we have found that it is a particularly effective strategy as part of treatment. Given that cognitive therapy involves a process of reattribution in which the panic sufferer is helped to understand that the symptoms which they experience do not arise from the feared catastrophes, the most effective way of doing this is to provide the person with an alternative, noncatastrophic explanation (the personalized vicious circle model). The paired associates can be a particularly powerful way of convincing the sufferer of the validity of the vicious circle model. A personalized version of the paired associates is used (derived from a careful assessment of the symptoms experienced and the misinterpretations made by that person). If the person begins to panic, they are asked what they make of the experience. If reading these particular pairs of words can induce panic, how does that fit with the idea that your symptoms mean that you are having a heart attack? How does this fit with the vicious circle explanation?

We have also discovered, in the context of therapy, that quite simple strategies will readily modify panic patients' response to the task. For example, a patient undergoing therapy was concerned that her initial panic when reading the paired associates meant that she was so out of control that even reading words on a card could make her have a panic. She was asked to read the same card, but where the hyphen appeared in the pair (e.g., breathless-suffocate) she was to say "does not mean I will." This procedure completely abolished her anxious response to the card. When asked what she had learned, she replied that she now understood that changing the meaning of panic symptoms was the key to dealing with panic attacks, and that she did not need to exercise control over panic. This clinical illustration shows both the potential strengths of the technique and the dangers of its uncritical use.

6.18.7.1.1 Cognitive therapy for panic: some general issues

Cognitive therapy has similar prerequisites to other forms of psychological treatment; primary among these is the formation of a good, collaborative therapeutic relationship. The style of therapy emphasizes guided discovery, so that the patient is helped to understand and try to modify their problems by using careful questioning. Therapy also makes extensive use of diaries and other aids; a particularly helpful adjunct to the most efficient use of treatment time is to tape record therapy sessions so the patient can listen to the tape at home. These elements are considered to be a minimum baseline against which any effective therapy needs to be judged. The general cognitive theory predicts that specific techniques will be of minimal effectiveness in the absence of a good therapeutic relationship as described above. Part of this relationship involves a proper assessment of the idiosyncratic problems experienced by the person in their own unique individual context. Therapy is based on the view that if a person holds a "distorted" belief, this is because they have good present, contextual, and historical reasons for doing so. This is equally true not only in the obvious case of general feelings of low self-worth in a person whose main difficulty is low self-esteem, but also for specific misinterpretations of bodily sensations in someone suffering from frequent panic attacks. For example, it is often important not only to pinpoint just what the person means by the idea of losing control, but also loss of control is a major issue for them. Most commonly, these types of concern reflect "developmental" issues.

Evaluation of specific techniques or strategies must therefore take place against the necessary background of good and consistent general therapeutic skills. People (clients and therapists) seldom work well with those who they tend to distrust. Many of the negative findings in the field can be explained not only by the failure of the specific intended manipulation (which is, of course, a fatal error) but also by inappropriate therapy styles. One of the most common errors in this respect is the use of cognitive-behavioral treatments in a prescriptive fashion. Another example is to abstract a single element (e.g., the emphasis by some on "correct breathing," by others on "positive thinking"). In order to ensure therapy integrity, therapy evaluations need to combine assessment of specific techniques with the evaluation of therapy style and quality of relationship. Other factors which are of key importance (and which need to be equated across any more refined comparisons of different therapies) are therapist time, the initial credibility and expectation of improvement engendered by the different treatments prior to any differential treatment effects, any assessments and self-monitoring, and so on.

6.18.7.1.2 Clinical implementation of cognitive-behavioral therapy

Once it has been established that panic is a major problem for the person and a more general assessment of the patient's situation has been carried out, a specific panic-oriented assessment is undertaken. This assessment focuses on eliciting an account of recent panic attacks and devising an individualized vicious circle explanation of the sequence of events during panic (loosely based on Figure 1, but always tailored to the idiosyncratic description of the patient). The links which comprise the vicious circle should be elicited by systematic questioning, thus ensuring both that the assessment is accurate and that the patient is clear about the way in which the formulation has been reached. The patient has to recall the last major panic they experienced, and then to describe, step by step, how it developed.

Questioning is guided by use of the sequence in the upper part of Figure 3, leading to the construction of a vicious circle as shown the lower part of the figure. Thus, if the first thing the patient noticed was a physical sensation, the next question should concern the way the patient interpreted it (e.g., "When you noticed your heart pounding, what went through your mind at that time?"). Another question which may be useful at this crucial stage in the assessment is "Right then, at that time, what did you think was the worst thing that could happen?" Once a specific catastrophic thought (or image) is elicited, questioning shifts to the anxiety experienced (e.g., "When you had the thought, "I'm having a heart attack,' how did that make you feel?"). The next question concerns physical reactions to anxiety (e.g., "when you became anxious about having a heart attack, how did that affect you physically?"). Once the vicious circle has been elicited in this way, it is summarized verbally and outlined on paper for the patient. Thus, in the above example, the summary would go: "Let's see if I have understood what you are telling me.

During the attack you experienced on Wednesday night, you first noticed your heart pounding. You then had the thought 'I'm having a heart attack,' and this, not surprisingly, frightened you. The anxiety made your heart pound more, which seemed to confirm the idea that you were having a heart attack, and so on, round in a vicious circle as I've drawn here. Does that seem to you to be right?" In this way, a positive description of the factors involved in the production of panic is built up from information provided by the patient. Note that the emphasis is on providing a positive, noncatastrophic account of panic rather than on disproving feared catastrophes. The internal logic of panic is emphasized as a way of normalizing the intensity of the anxiety experienced (e.g., "How do you think that anyone would feel if they noticed that they were feeling dizzy and believed that this meant they were about to faint? ... When someone becomes anxious because they have a very frightening thought, such as about having a heart attack, how do you think they would feel physically?").

A helpful pointer for the assessment, and a further illustration of the logic of panic, is the way in which catastrophic interpretations tend to be meaningfully associated with particular symptoms. Examples of the way in which this association works are illustrated in Table 2. Assessment as described above is the first component of treatment, because it already involves a major element of decatastrophizing, helping patients to make sense of the panics which had previously been especially frightening because they appeared to be inexplicable. The procedures used for further decatastrophizing are divided into verbal techniques, in which discussion of the patients' past experience is used to change beliefs and behavioral experiments, in which the patient and therapist devise experiments to test the way in which particular processes may be involved in panic attacks.

(i) *Discussion.* The vicious circle model is again the starting point for discussion aimed at helping the patient to attribute the symptoms they experience during panic away from catastrophic explanations and on to less threatening interpretations. The therapist starts from the assumption that, if the patient makes catastrophic interpretations, they do so because they have evidence which they find convincing. This evidence may be past experiences (e.g., a close relative or friend who experienced similar symptoms associated with serious illness), in generalized attitudes (e.g., "If I can't control my thoughts I will go mad"), in the intensity or nature of the physical sensations themselves (e.g., "I feel so faint that I must be about to pass out"), and so on.

Discussion involves helping the patient to evaluate such evidence and consider alternatives. For example, assessment of a patient revealed that, during panic, she interpreted dizziness, unsteadiness, and feelings of unreality as a sign that she was about to faint or collapse. Attacks invariably started with an episode of dizziness, often triggered by postural change or feeling angry and frustrated. The evidence for her belief that she would faint was that the symptoms, especially faintness, became very intense when she was at the height of an attack, and that she had, on a previous occasion, fainted. During the first stage of this discussion, the patient and therapist went over the factors involved in a true faint, and agreed that a drop in blood pressure was required in order to faint. The patient, when asked what she thought might happen to her blood pressure during panic, said that she knew that it went up a little and this therefore must mean that she could not faint during panic. The discussion then moved on to her previous fainting episode, which had occurred after giving blood. The reasons for blood pressure drop in this specific situation were discussed. The patient was also asked to compare the experience of fainting with the experience of feeling faint in panic; she identified these as quite different. In particular, she noted that when she fainted she was not anxious, but instead became rather sleepy and distant. When asked whether that distant feeling resembled the unreality she experienced during panic, she said that it was quite different, and summarized by saying that she would easily recognize a true faint if it were to occur, and that fainting was particularly unlikely during panic attacks. This was an especially useful manoeever, because it meant that previously anxiety-provoking situations had now become safety signals. Following on from this, the discussion moved on to consideration of the nature of "feeling faint," and whether such feelings were necessarily associated with the fact of fainting. The comparison with having a splitting headache was used; did a splitting headache mean that one's head could split? The patient agreed that this was unlikely and her ratings of belief in the idea that she might faint during a panic attack dropped substantially, but not completely. When questioned about the basis of her beliefs, she said that the symptoms were so intense at the time she believed that there had to be something wrong that could lead her to faint. The therapist then asked her if she had been excited recently. She said that she had. Three weeks previously, she had thought that she had won a very large sum of money (on the football pools). She described her bodily sensations at that time, which were almost identical in type and intensity

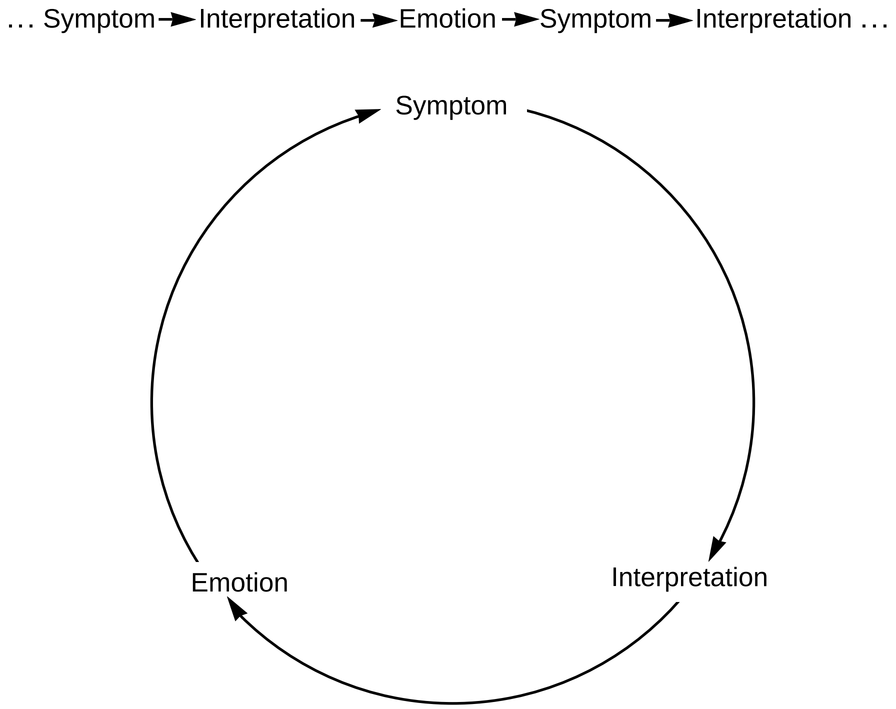


Figure 3 Construction of a vicious circle.

to those she experienced during a panic, although she had not panicked and found the experience pleasurable and exciting. Careful questioning elicited the main difference to be the way in which she interpreted the sensations of excitement; she had not had any catastrophic thoughts. The conclusion she drew from this discussion was that the symptoms she experienced during panic attacks were the normal effects of adrenaline, and not a sign of something physically amiss. Finally, ways in which the patient could apply the reasoning outlined above during panic attacks were devised and discussed.

(ii) *Behavioral experiments*. Discussion in which the evidence upon which patients base their catastrophic misinterpretations is reviewed continues throughout therapy. However, patients sometimes do not have ready access to information which would help them to challenge their misinterpretations, or understand the alternative explanations which have been generated in the course of discussion but require further evidence to support the alternative. This is where behavioral experiments are particularly valuable as part of treatment. A wide range of behavioral experiments are useful. One of the most commonly used involves the use of hyperventilation, which often occurs in association with panic when the associated symptoms are misinterpreted. The metabolic alkalosis which accompanies hyperventilation produces a wide range of physical symptoms, such as tachycardia, dizziness, paresthesia, breathlessness, and so on; these symptoms are a particularly potent basis of misinterpretation because they are often relatively unfamiliar to the patient in the context of his or her previous experience of anxiety (e.g., paresthesia and dizziness).

Particularly common is the experience of breathlessness, which, if misinterpreted as a sign of impending suffocation, can have the effect of making the patient try to breathe more, worsening the breathlessness, and so on. An especially helpful way of dealing with this is to ask the patient to show how he or she breathes (or tries to breathe) at the height of a panic attack. If the pattern the patient demonstrates appears to involve an element of hyperventilation, the therapist asks the patient to continue to breathe in the same way (or, if it is only a slight degree of hyperventilation, to exaggerate this) for a few minutes, then to describe the physical feelings they experience. This type of procedure reproduces the bodily sensations experienced during a panic attack by about 50%; the fact that the patient is simply doing what they would normally be doing during a panic makes this demonstration of the role of hyperventilation particularly convincing to him or her. Discussion of the extent to which the experience of deliberate overbreathing was similar or different from the patient's naturally occurring panic will usually show that the physical sensations were similar, but the experience differed in the extent to which anxiety was present. This, of course, is because the patient in the therapist's office has an unambiguous and nonthreatening explanation of their symptoms, and because the patient is in control of the onset (and therefore the offset) of the symptoms themselves. This difference can itself help pinpoint the crucial role of misinterpretations; thus, the patient is taught that hyperventilation does not cause panic, but is a likely source of symptoms which can be misinterpreted. Subsequently, patients may find it helpful to learn simple breathing control techniques which they can use during panic attacks as part of the general cognitive strategy. It is important to stress that breathing control is a helpful way of dealing with the nuisance value of symptoms, but only at times when the patient notices the physical symptoms. It emphasizes that the control of breathing is in no way essential; indeed, in the later stages of therapy the patient deliberately hyperventilates in situations which tend to make them anxious; this exercise provides further confirmation of the noncatastrophic nature of bodily sensations. Throughout, the emphasis is on the idea that the key factor is misinterpretation; breathing control is most useful as evidence for a noncatastrophic interpretation of the symptoms. During an acute attack, the patient reminds him- or herself (a) that the physical symptoms of panic were reproduced by overbreathing in the therapist's office, suggesting that the symptoms are both a sign of anxiety induced by catastrophic misinterpretations and also a result of stress-induced hyperventilation, and (b) that strategies which help them to control their thoughts and breathing, although unnecessary for their safety, have the effect of reducing the symptoms, thus providing further confirmation of the noncatastrophic interpretation. (Note that, despite encouraging early clinical reports, breathing control without the crucial cognitive element has been shown to be ineffective; the cognitive element appears to be necessary for successful treatment using respiratory control.)

The therapist who wishes to deal effectively with the problems of patients suffering from panic attacks should also deal with those safety-seeking behaviors which the patient uses during panic attacks. Typically, three main types of behavior are seen: (a) avoidance of situations which the patient believes might provoke panic (e.g., avoiding supermarkets); (b) escape from a situation when a panic attack occurs (e.g., leaving a shop once the symptoms of panic begin); and (c) safety-seeking behaviors carried out during panic with the intention of actively preventing the feared catastrophe (e.g., when dizziness leads to the thought "I'll faint," holding on to another person, shopping trolley, or sitting down). Each of these behaviors can have the effect of maintaining the panic-related beliefs; the patients logically infer that they have prevented the occurrence of feared catastrophes by their behavior (e.g., "If I had gone to the supermarket yesterday, then I would have passed out; If I had not left immediately I would have fainted; If I had not sat down then I would have fainted." Thus, behavior of the type described above prevents disconfirmation of the feared catastrophes, and transforms potential disconfirmations into "near misses." In cognitive therapy for panic, patients are helped to understand how their behavior can maintain anxiety (in the same way as outlined above), and the therapist helps the patient to use this information to construct an explanation of the persistence of their beliefs. For example, a patient summarized this as "Although I believe that my behavior has prevented disaster, maybe this is only because I have never tried to check this out, and have just assumed that my *not* fainting was because of the precautions I took. By continuing to behave *as if* I might have a heart attack might have kept my anxiety going, because it was a constant reminder that I have to be careful, that I am vulnerable. I have never given myself the opportunity to test the truth of my fears." The therapist uses the patient's understanding of how behaviors can prevent disconfirmation of feared disasters to devise direct tests; for example, a patient who felt weak during attacks and believed that she was going to fall would tense her muscles to prevent collapse. In the office therapy session, patient and therapist tried out how weak muscles would have to be to result in collapse. The patient decided to test the possibility of falling at times when she felt panicky and weak by trying to relax her muscles in the same way she had in the therapy session. This exercise had the effect of completely changing her belief in the possibility of collapsing, integrating cognitive techniques with short behavioral experiments. These behavioral experiments, in which the patient experiences a clear disconfirmation of the beliefs which had previously been the focus of safety-seeking behavior, allow rapid and complete modification of both avoidance behavior and catastrophic interpretations.

6.18.7.1.3 *Effectiveness of cognitive-behavioral therapy*

Early clinical studies on both cognitive and behavioral treatments used consecutive single case series (see Salkovskis & Clark, 1986, and Barlow, 1988, for a review of these). These early studies used quasiexperimental designs which required the measurement of a baseline, followed by the demonstration of change associated with treatment that was greater in magnitude than any variation seen during the baseline period. Not only was it possible to show this, but it was also shown in these relatively unselected samples that the changes associated with treatment (most patients being panic free at the end of treatment) persisted at two-year follow-up. These studies were criticized for not being sufficiently selective about the patients included and not adhering exactly to a preset treatment protocol. For example, several of the patients in Clark, Salkovskis, and Chalkley's (1985) study required and were given additional treatment for nonpanic related problems. As these people were treated as part of routine clinical practice, a certain (small) amount of time was devoted to dealing with problems such as assertiveness difficulties, marital problems, and so on. This was fully documented in the published report, but was nevertheless a source of some criticism, and highlighted the need to conduct better controlled studies. A later single case series (Salkovskis, Clark, & Hackmann, 1991) was used in a quite different way. In this series, it was demonstrated that it was possible to make a substantial impact on panic attack by using brief (two hour) and purely cognitive (verbal) procedures. This study was consistent with the hypothesis that cognitive change (focusing on the modification of the misinterpretation of bodily sensations) could be an element in the effectiveness of cognitive therapy for panic in reducing panic attack frequency. This study also gathered preliminary evidence that cognitive procedures which do not target misinterpretations may not be effective.

Following these clinically based studies which demonstrated that the effectiveness of cognitive therapy was unlikely to be due spontaneous remission or to nonspecific factors (see also Beck, 1988), it was clearly important to assess the effectiveness of cognitive therapy compared with the best available alternative psychological and pharmacological treatments. Clark et al. (1994) compared cognitive therapy to (i) a waiting list control group; (ii) imipramine delivered in the optimum fashion by an experienced biologically-oriented psychiatrist (gradually increased to high doses maintained to six months then gradually tapered); (iii) applied relaxation, a specially modified form of relaxation for use with panic (Ost, 1988); and (iv) cognitive therapy. All active treatments were delivered by experienced therapists in the fashion currently considered optimum for each therapy; thus, psychological treatments were 12 sessions over 12 weeks, pharmacotherapy was continued for much longer.

Important features of this study were (i) the selection of patients who were particularly unlikely to show spontaneous remission (i.e., those patients experiencing frequent panic attacks with a minimum duration of six months); (ii) delivering each treatment in an optimum fashion, with considerable care being taken with treatment integrity (e.g., sessions audiotaped and checked against the competency scale for cognitive therapy adapted for panic treatment); (iii) ensuring that each treatment had an equally credible rationale and expectance of good outcome at the outset (i.e., before any differential effectiveness was apparent); (iv) the inclusion of as many common elements as possible (e.g., daily recording/self-monitoring, printed therapy handouts early in treatment, self-exposure instructions in the later stages of treatment, and so on); (v) use of blind assessor ratings as well as self-ratings; (vi) inclusion of high end-state functioning criteria in outcome assessment; (vii) maximum attention to follow-up completeness; and (viii) inclusion of theoretically relevant variables to predict relapse.

The outcome of this study clearly indicated (i) that all three treatments were active (superior to waitlist); (ii) that both in the short term (12 weeks) and long term (one-year post-treatment follow-up), cognitive therapy was significantly superior to both applied relaxation and imipramine; (iii) that the degree to which catastrophic misinterpretations of bodily sensations remained at the end of treatment predicted relapse at one-year follow-up, and that this remained the case when any residual symptomatology at the end of treatment was partialled out; and (iv) that all treatments resulted in good levels of high end-state functioning at the end of treatment and at one-year follow-up (CT 80% and 70%; AR 25% and 32%; imipramine 40% and 45%).

The particular effectiveness of cognitive therapy has been replicated in a number of centers; a recent feature of this work has been the coordination of outcome measures allowing detailed comparisons across centers (Clark, 1994). Treatment outcome studies are also described particularly well in Clark (1994).

The next stages in this line of research is to (i) improve cost-effectiveness, that is, to evaluate whether it is possible to conduct treatment in a smaller number of sessions without sacrificing the outstanding results found by our own and other groups, and, if a briefer treatment is found to be as effective. Work carried out by the Oxford group on the treatment of panic disorder suggests that it is possible, by the use of self-help manuals integrated with therapist contact, to reduce therapy time to around five sessions without loss of efficacy (Clark et al., in preparation); (ii) to return to the initial strategy of applying the therapy to a less selected clinical sample of people suffering from panic attacks; (iii) to evaluate the generalizability of cognitive methods and theory developed in panic by adapting these to the needs of other patient groups such as hypochondriasis (Salkovskis, 1989; Salkovskis & Clark, 1993; Salkovskis & Warwick, 1986; Warwick & Salkovskis, 1990).

It is important to note that a range of other psychological treatments have been shown to be more or less effective in the amelioration of panic attacks, including applied relaxation (Ost, 1988), exposure to interoceptive sensations (Hout van den et al. 1987), paradoxical intention (Mitchelson, Mavissakalian, & Marchione, 1988) and a treatment which combines elements of traditional cognitive therapy, respiratory control, and relaxation, termed Panic Control Treatment (Barlow, 1991; Barlow & Cerny, 1988). Barlow (1997) suggests appropriately that some caution is needed before concluding that psychological treatments have been fully developed to be effective in the long term.

6.18.8 CONCLUSION

Both biological and psychological theories have generated a great deal of specific research into Panic Disorder and its treatment. Over the last decade, the evidential basis for psychological approaches has strengthened, in large part as a result of the specific predictions made both for experimental and clinical studies. By contrast, biological theories have been been gradually weakening. Nevertheless, there is a specific need to consider further the nature of the links between catastrophic interpretations and acute panic and physiological and behavioral correlates. Such clarification should improve the extent to which the misinterpretations hypothesis can be matched against findings from the biological and behavioral fields, and allow yet more specific predictions to be made in these areas. The clinical benefits of a more coherent approach to the conceptualization of panic attacks, Panic Disorder, and associated phenomena would be considerable.

6.19.1 NORMAL AND PATHOLOGICAL WORRY

Research on worry began in the test anxiety area in the 1970s, where the distinction was made between worry as a cognitive aspect of anxiety and emotionality reflecting the physiological features of anxious experience. An early definition of worry suggested that it involved "a chain of thoughts and images, negatively affect laden and relatively uncontrollable. The worry process represents an attempt to engage in mental problem solving on an issue whose outcome is uncertain but contains the possibility of one or more negative outcomes. Consequently, worry relates closely to fear process" (Borkovec, Robinson, Pruzinsky, & DePree, 1983a). So the early theoretical view of worry was that it was a cognitive avoidance response to detected threat (Borkovec, Metzger, & Pruzinsky, 1986). Several studies indicated that worry was indeed functionally separate from somatic anxiety and that it was primarily responsible for the interfering effects of anxiety on test and grade performance (Deffenbacher, 1980). During the 1980s, experimental research devoted to exploration of the nature of the worry process began. Inductions of worry were found to produce several important effects: incubation of negative thought intrusions (Borkovec et al., 1986; Pruzinsky & Borkovec, 1990; York, Borkovec, Vasey, & Stern, 1987), lengthening of decision-making times (Metzger, Miller, Cohen, Sofka, & Borkovec, 1990) due to elevated evidence requirements (Tallis, Eysenck, & Mathews, 1991), absence of change in heart rate (Borkovec et al., 1983a; York et al., 1987), elimination of the incubating effects of unconditional stimulus rehearsal in the unconditioned stimulus revaluation phenomenon (Davey & Matchett, 1994), and the generation of predominantly anxious but also depressive affect (Andrews & Borkovec, 1988). Remarkably, nonanxious groups displayed the very same effects during or after brief elicitation of the worry process. Related research indicated that anxious thoughts were harder to dismiss than neutral or depressing thoughts or intrusive negative images. Such research also showed that both the degree of worry about anxious thoughts and the presence of depressed states could further decrease control over anxious thoughts (Clark, 1986; Clark & DeSilva, 1985; Edwards & Dickerson, 1987a, 1987b; Sutherland, Newman, & Rachman, 1982). What generally emerged from this literature was that normal negative intrusive thoughts (including those of worry) were distinguishable from the pathological worry found in anxiety disorders by neither their process nor effects but rather by their frequency and intensity, which in turn appeared to be due to their uncontrollability (Clark, 1986; Clark & DeSilva, 1985; England & Dickerson, 1988; Kent & Jambunathan, 1989; Parkinson & Rachman, 1981; Salkovskis & Harrision, 1984). Despite growing interest in the phenomenon of worry during this period, the greatest boost to its investigation occurred when worry became the central defining feature of generalized anxiety disorder.

6.19.2 DIAGNOSTIC DESCRIPTION OF GENERALIZED ANXIETY DISORDER

The diagnostic description of generalized anxiety disorder (GAD) has undergone several changes in diagnostic definition. The label first occurred in the third edition of the *Diagnostic and statistical manual of mental disorders* (*DSM*, American Psychiatric Association, 1980); the older category of anxiety neurosis was divided into panic disorder and GAD. The definition of GAD focused on chronic, diffuse anxiety and its symptoms of apprehensive expectation (worry), vigilance/scanning, motor tension, and autonomic hyperactivity. If other Axis I conditions were present, however, GAD was not to be diagnosed. The arrival of *DSM-III-Revised* (American Psychiatric Association, 1987) was an important turning point. GAD was allowed as a principal diagnosis even in the presence of most other disorders, and it was centrally defined as apprehensive expectation (worry). Its remaining symptoms were organized into an 18-item checklist and designated as associated characteristics.

Further revision occurred in *DSM-IV* (American Psychiatric Association, 1994) based on comprehensive reviews of the extant empirical literature on GAD (Borkovec, Shadick, & Hopkins, 1991). The disorder is now defined by excessive and uncontrollable worry about a number of events or activities not confined to other Axis I disorders, occurring more days than not for at least six months, causing clinically significant distress or impaired functioning, and not due to the direct physiological effects of a substance or a general medical condition. The associated symptoms checklist was reduced in size, based on empirical identification of the most frequent and reliable symptoms (Marten et al., 1993). Diagnosis requires the presence of only three of six symptom groups (restless/keyed-up/on-edge, fatigue, difficulty concentrating, irritability, muscle tension, and sleep disturbance). Interestingly, all six symptoms reflect central nervous system (CNS) rather than autonomic nervous system (ANS) activity, matching what has been discovered in the psychophysiology of GAD. Also of importance for the scientific generalizability and continuity of GAD research, clients who meet GAD criteria by *DSM-III-R* routinely meet *DSM-IV* criteria as well (Abel & Borkovec, 1995).

6.19.3 IMPORTANCE OF GAD

GAD may be a particularly important area of experimental outcome and basic research. In terms of psychopathology: (i) estimates in the 1990s (Kendler, Neale, Kessler, Health, & Eaves, 1992; Wittchen, Zhao, Kessler, & Eaton, 1994) suggest 3.6–5.1% lifetime and 3.1% one-year prevalence rates, and it is one of the most common comorbid conditions in the anxiety and mood disorders (Brown & Barlow, 1992); (ii) it may be the basic anxiety disorder (based on its early onset, chronicity, and resistance to change) out of which other anxiety disorders often emerge (Brown, Barlow, & Liebowitz, 1994); (iii) worry, the central feature of GAD, is pervasive in the anxiety and mood disorders (Barlow, 1988); (iv) worry has been experimentally demonstrated to prevent emotional processing and thus may maintain any disorder wherein such processing is important for therapeutic change (Borkovec, 1994); and (v) successful treatment of GAD results in dramatic reduction in comorbid conditions (Borkovec, Abel, & Newman, 1995). So understanding the mechanisms of GAD and developing effective therapies based on that understanding may not only contribute to the amelioration of a very common disorder which is difficult to treat but may also have significant implications for the treatment and/or prevention of other disorders. Investigation of GAD is also important in the more general pursuit of understanding human nature and its adaptive and maladaptive processes. Research on GAD and worry has implicated the mutually interactive influences of several response systems (e.g., attention, interpretation of the environment, implicit and explicit memory, abstract thought, imagery, affect, central and peripheral physiology, and behavior) in their processes and maintenance. Thus, the study of GAD may yield knowledge in general, about the nonlinear dynamical nature of human functioning, viewed as a constantly changing process in response to a changing environment. Finally, recent basic research on GAD, especially on the role of developmental and interpersonal factors, holds considerable promise for the development of more effective therapy.

6.19.4 BASIC RESEARCH ON THE NATURE, FUNCTIONS, AND ORIGINS OF WORRY AND GAD

Clinical experience and empirical results suggest a straightforward description of the inner life of GAD clients: it is necessary to search constantly for cues about possible future threat ("What if ...?") in order to avoid catastrophes or to prepare ways to cope with their occurrence (Beck & Emery, 1985). Because the dangers exist only in their minds and only in the future, behavioral avoidance is not an available response. This leaves conceptual activity (i.e., worry) as one of the few coping resources. Human thought may well have evolved specifically to anticipate the future, to avoid negative events, and to increase positive events (McGuire & McGuire, 1991). The central questions for GAD research, however, focus on why so much threat is perceived, what the specific nature, functions, and consequences of the pathological worry response to threat might be, what factors are involved in its origins and maintenance, and how it is best treated. Results suggest that the answers will likely be found in dysfunctional processes within and interactively between three domains: information processing, physiology, and interpersonal functioning.

6.19.4.1 GAD and Information Processing

Evidence indicates that GAD and its central worry feature are associated with impairments in several types of information processing, the most important of which is the processing of emotional material.

6.19.4.1.1 Worrisome thinking and emotional processing

When people worry, they are mostly talking to themselves. Worry involves a prevalence of abstract, verbal-linguistic, thought as opposed to imaginal process (Borkovec, 1994). This is true for GAD clients and nonanxious controls when they are worrying. During relaxation states, GAD clients continue to experience the predominance of thoughts, whereas nonanxious persons shift to a predominance of imagery. Therapy for GAD clients leads to the normalization of thought and image frequencies (Borkovec & Inz, 1990). The extensive findings on the role of such cognitive factors and many others in GAD (Mathews; 1990; Mathews & MacLeod, 1994) has long suggested the usefulness of cognitive therapy (CT) for the disorder.

The role of such cognitive factors is also fundamental to a specific theoretical view of the nature and functions of worry. The distinction between thought and imagery is crucial. Imagery is closely tied to efferent commands into the affective, physiological, and behavioral systems; thought is not. Imagination of fear material elicits strong cardiovascular response; verbally articulating the same material does not (Vrana, Cuthbert, & Lang, 1986). It is adaptive that thought evolved in this way. Its relative isolation from efferent systems increases choice and flexibility.

Worrisome thought, however, has the disadvantage that it precludes emotional processing. Phobic persons who think worrisome thoughts just prior to repeated phobic image presentations show no cardiovascular response at all to those images; those who think neutral or relaxing thoughts display significant response, with relaxation producing habituation over repeated images (Borkovec & Hu, 1990; Borkovec, Lyonfields, Wiser, & Diehl, 1993a). Moreover, worry after exposure to a stressful event also results in a failure to process the emotional material adaptively (Butler, Wells, &

Dewick, 1995; Wells & Papageorgiou, 1995). From a neobehavioristic perspective, absence of cardiovascular response to phobic information reflects a failure to access the complete fear structure stored in memory (especially its efferent emotional meanings) and therefore an absence of the kind of emotional processing necessary for extinction (Foa & Kozak, 1986). One of the immediate functions of worry, then, is the avoidance of aversive images, somatic anxiety, and other negative emotions, and the worrying is thereby strengthened via negative reinforcement. A significant consequence of this avoidance function is the maintenance of anxious meanings despite daily exposures to threat-related material and the potentially corrective information that accompanies such exposures. These findings and their theoretical context have long suggested the usefulness of imagery exposure (combined with relaxation) for accessing and changing emotional meaning in therapy for GAD.

The above research supports the hypothesis that worry functions as a cognitive avoidance response to threatening material. Analogue GAD and control groups actually view worry in a similar way (Borkovec & Roemer, 1995). When these groups rated possible reasons for worry, only one scale discriminated the two groups: "Worrying about most of the things I worry about is a way to distract myself from worrying about even more emotional things, things that I don't want to think about." Although this could merely represent attempts of the GAD participants to rationalize why they worry, it may also reflect a further avoidance function of worry: avoidance of more painful emotional material. Rather than focus on primary affect, the superficial content of worry may be focused on secondary or instrumental affects.

What underlying content might be avoided is speculative, but three candidates exist, and all relate to interpersonal issues. Two (negative attachment experiences and current interpersonal problems) are discussed later. The third possibility resides in the fact that both GAD clients and analogue GAD groups report more frequent past traumas than controls, and 65% of these are interpersonal in nature (Roemer, Borkovec, Posa, & Lyonfields, 1991). Of course, when considering this evidence, we must be mindful that recall is subject to distortion, the traumas could have occurred after the onset of GAD, and many psychiatric groups report frequent trauma. However, content analyses of the trauma topics and worry topics reveal indirect evidence for avoidance of trauma memories (Shadick, Roemer, Hopkins, & Borkovec, 1991). Even though the traumatic events involved death, illness, or injury related to self or others (as required by *DSM* trauma definition), this is the very category about which GAD clients worried the least. The avoidance of trauma content can in and of itself lead to the maintenance of anxious meanings, but a traumatic experience may also provide actual evidence that the world (especially involving other people) can indeed be a threatening place and further contribute to the origins and/or maintenance of GAD.

The implication of worry's function as cognitive avoidance and its prevention of emotional processing is far-reaching. Worry contains a process that maintains GAD or indeed any emotional disorder. Emotional change due to daily life experiences or to deliberate exposures in therapy to emotional material is less likely to take place to the degree that worry is present before, during, or after such exposures.

The mechanisms for worry's inhibitory effect on emotional processing are unsubstantiated, but four possibilities have been suggested (Borkovec, 1994): (i) lessened attentional resource for processing other information (Mathews, 1990); (ii) difficulty of shifting attention from excessive, habitual (especially negatively valanced) thought activity (Parkinson & Rachman, 1981); (iii) semantic satiation effects of repetitious worrisome thought, thus insulating worry content from the rest of its associative network, especially affective associations (Smith, 1984); and (iv) less mismatch between information expected and received (a central condition for anxiety in Gray's neuropsychological theory of anxiety (Gray, 1982)). Future basic research might aim usefully at isolating the specific mechanisms involved.

6.19.4.1.2 Worrisome thinking and other information processing functions

Research evidence indicates that GAD and worry are associated with various information processing characteristics that interfere with learning from experience and thereby maintain anxious meaning. GAD clients display (i) preattentive bias to threat cues, even outside of awareness and often with task-interfering effects, (ii) rapid cognitive avoidance of detected threats such that explicit memory for the material is reduced but implicit memory is increased, and (iii) negative interpretations of and predictions from ambiguous and even neutral information. Several of these effects are accentuated for stimulus material directly associated with the client's worrisome concerns (Mathews, 1990; Mathews & MacLeod, 1994).

Three further instances of worry effects on information processing have emerged. First, in the current therapy trial at the Pennsylvania State GAD Project, clients monitor their daily worry predictions and rate actual outcomes once they occur. In this study, the outcomes turned out better than expected 84% of the time, and in 78% of the remaining situations, clients still coped better than they predicted. Thus, in only 3% of all worries did the core feared event ("The predicted bad event will occur, and I won't be able to cope with it") actually happen. It is possible that GAD clients continue to worry despite consistent real world evidence that feared outcomes do not occur because they frequently fail to process this corrective evidence. Second, people who worry about a topic prior to generating alternative predictions of what might happen generate exclusively negative predictions, whereas people who relax before generating the alternatives list only positive predictions (Borkovec, 1995). This suggests that worrying increases cognitive rigidity and that this rigidity precludes the retrieval of realistic corrective information. Third, several studies have demonstrated poor recall (reflecting cognitive avoidance) of threat words in GAD (cf. Mathews, 1990). However, a study by Thayer and Borkovec (1995) attempted to replicate these findings using a higher-order classical conditioning task (i.e., emotional words as the unconditional stimuli). In this study, GAD clients were exposed to 10 threat words (preceded by a colored block, the conditional stimulus) and 10 nonthreat words (preceded by a differently colored block) in random order. Clients merely read the words silently as they appeared, but they were given a surprise recall task at the end. Contrary to results of prior research, clients recalled more threat than nonthreat words and to a greater degree than nonanxious participants. Whereas previous research was based on brief exposures and/or instructions to actively respond to the words, Thayer and Borkovec used a longer exposure time. This suggests that lengthier exposures during a passive task will enhance threat recall from explicit memory, perhaps by overriding the defensive process of cognitive avoidance.

Taken as a whole, the above research indicates that GAD is characterized by habitual, inflexible cognitive and affective processes. A parallel rigidity has also been found in the tonic physiology of GAD and the phasic physiology of worry.

6.19.4.2 The Psychophysiology of GAD

Unlike the results from other anxiety disorders, physiological activation is not always characteristic of GAD, and inductions of worry do not produce differential activation compared to relaxed states (Borkovec et al., 1983b; Elliott, 1990). One study did find greater CNS-mediated muscle tension in GAD but no other activation differences compared to controls (Hoehn-Saric, McLeod, & Zimmerli, 1989). However, GAD was characterized by reduced variability in autonomic measures, leading to the hypothesis that GAD involves sympathetic inhibition and an autonomic inflexibility rather than sympathetic activation (Hoehn-Saric & McLeod, 1988).

Rigid autonomic functioning is implicated in several biological disorders (Thayer, Friedman, & Borkovec, 1996). Models of nonlinear dynamical systems view flexible responding as a marker of system integrity, and these models interpret reduced variability to be pathological (Goldberger, 1992). The hypothesis that GAD is characterized by a distinctive physiology involving restricted range of variability thus takes on added importance. However, the speculation that this is due to sympathetic inhibition may be an oversimplification of complex autonomic activity which involves both sympathetic and parasympathetic branches.

Evidence supports the specific importance of chronic parasympathetic (vagal) deficiency in GAD. Analogue GAD participants display tonically lowered vagal tone and little variation in either vagal tone or heart rate during rest, aversive imagery, and worrisome thinking (Lyonfields, Borkovec, & Thayer, 1995). Nonanxious participants show decreases in vagal tone from rest to emotional tasks and the greatest reduction during worry. Thus, GAD is characterized by autonomic inflexibility, such rigidity is due to a chronic deficiency in parasympathetic tone, and worrisome thinking can cause such reductions. Replicated findings emerged from a comparison of GAD clients to nonanxious participants during periods of self-relaxation and worry (Thayer et al., 1996). GAD was characterized by a tonic deficiency in vagal tone, and a main effect of tasks indicated that worry phasically caused that deficiency in GAD and nonanxious participants. These results make dramatic sense if we combine what is known empirically about GAD (e.g., chronic vigilance to threat, frequent aversive cognitions with a predominance of worrisome thought, excessive muscle tension, and difficulty concentrating) with results from experimental physiology: tasks that phasically cause reduced vagal tone among normals include threat of shock, recall of past aversive events, mental problem-solving, and isometric hand-grip (Grossman, Stemmler, & Meinhardt, 1990; Grossman & Svebak, 1987). Moreover, vagal deficiency provides a physiological basis for the habitual, GAD-characteristic attentional processes mentioned previously, given that poor attentional concentration and distractibility are related to lower vagal tone in both infants (Richards, 1987) and adults (Porges, 1992). The above research demonstrating vagal deficiency and autonomic inflexibility in GAD reinforces the long-held view of the usefulness of relaxation methods in the treatment of GAD. These results also provide a clear physiological basis for the finding that CNS but not ANS symptoms characterize the self-reports of GAD clients (Marten et al., 1993).

This GAD-distinctive inflexibility also makes sense when considering the psychological situation that GAD clients face. Their threats are illusory, exist only in their minds, refer to a nonexistent future, and are based on fears of events having a low probability of occurrence. The clients thus face an insoluble problem wherein fight-or-flight activation is inhibited because there is no one to fight and nowhere to flee, analogous to the freezing response of rats when motoric avoidance to feared stimuli is prevented.

Electroencephalogram (EEG) differences have also been discovered between nonanxious groups and both GAD clients and chronic worriers (e.g., greater frontal beta and less parietal alpha for the latter) as well as between relaxation and induced worry tasks (e.g., greater frontal and parietal beta during worry) (Carter, Johnson, & Borkovec, 1986; Inz, 1990). Importantly, inflexibility was also revealed in the cortical activity of GAD clients; lowered variability was found in alpha and beta over several laboratory tasks (Inz, 1990).

Although restricted, tonic cardiovascular functioning appears to be characteristic of GAD, a close look at phasic heart rate reactions to threatening material reveals that brief initial activation can occur. Results from the threat/nonthreat word conditioning task described earlier have shown that: (i) nonanxious participants showed larger orienting responses to threat and nonthreat words than GAD clients; (ii) their magnitude was related to resting vagal tone (described earlier to be deficient in GAD and intimately related to attentional mechanisms); (iii) the control group, but not GAD group, showed habituation of physiological response over both threat and nonthreat trials; (iv) GAD clients, but not the control participants, displayed heart rate acceleration (the classic "defensive response") to threat words; and (v) the GAD group, but not the control group, developed an anticipatory heart rate deceleration to the colored block preceding threat words but not to the block preceding nonthreat words (Thayer & Borkovec, 1995). The latter result indicates that classically conditioned orienting responses (indicating increased attention) emerge in GAD over repeated exposures to verbal threat material, and provides a basis both for GAD hypervigilence and for the generalization of threatening meaning via associative learning processes which depend solely on words as the unconditional stimulus. These results may have significant implications for understanding the interrelationships between the processing of verbal material, attention, associative emotional learning, and physiology in GAD.

Thus far, we have reviewed information on the intrapsychic patterns of GAD showing inflexible and repetitious cognition, affect, and physiology. Several lines of research have also explored the possibility of habitual patterns in overt behavior, particularly those in the domain of interpersonal functioning. Such research has found evidence for recurrent, problematic, interpersonal behavior as well as for possible connections between adult interpersonal styles and early attachment experiences.

6.19.4.3 GAD and Interpersonal Factors

For many years, researchers have known of a significant connection between GAD and interpersonal factors. Several lines of evidence have contributed to this knowledge. First, patterns of familial history in GAD (Noyes, Clarkson, Crowe, Yates, & McChesney, 1987; Noyes et al., 1992) along with a low degree of heritability (Kendler et al., 1992; Torgersen, 1986) imply that interpersonal developmental experiences may provide some etiologic foundation for GAD. Second, although GAD clients worry about many topics, they are particularly afraid of interpersonal situations: social phobia is the most frequent comorbid diagnosis for GAD (Barlow, 1988; Borkovec et al., 1995); trait-worry correlates more highly with social fears than with nonsocial fears (Borkovec et al., 1983b); content analysis of GAD worry topics reveals interpersonal concerns to be more frequent than any other domain (Shadick et al., 1991). Finally, worry involves a predominance of thought; thought is based upon language; language is based on social communication. Thus, some features of thought (talking to ourselves) are inherently interpersonal (Borkovec et al., 1991). Together, these observations suggest that a history of negative interpersonal experiences may contribute to the origins or maintenance of GAD, to current interpersonal functioning, to the maintenance of an excessive perception of threat, and/or to learned worrisome thought styles to cope with threat.

6.19.4.3.1 GAD and early childhood interpersonal factors

Bowlby (1982) was quite specific about hypothesized relationships between attachment and anxiety. If a child has a primary attachment figure who is repeatedly unavailable, the resulting insecure base may manifest itself in the child's developing mental models of the world as a dangerous, frightening place, with an overestimation of the probability and severity of feared events and an underestimation of coping resources. These mental representations are strikingly similar to those present in adult GAD. Indeed, diffuse anxiety was felt by Bowlby to be the typical consequence of some forms of insecure attachment.

The Inventory of Adult Attachment (IAA, Lichtenstein & Cassidy, 1991) is based on Main and Goldwyn's (in press) system for scoring their Adult Attachment Interview (George, Kaplan, & Main, 1985) and on Bowlby's attachment theory. Results using the IAA indicate that the GAD groups score higher than nonanxious groups on role-reversed/enmeshed relationships but not on childhood rejection (Borkovec, 1995). The child had to take care of the parent rather than the parent taking care of the child. This suggests an understandable basis for the adult GAD view of the world as a potentially dangerous place, of oneself as unable to cope, and of the need to constantly anticipate threats as the necessary means to obtain love, approval, and nurturance. The clients also reported greater unresolved feelings of anger and vulnerability toward their primary caregiver. Both the enmeshment and anger/vulnerable findings are discussed more fully below in relation to findings on adult interpersonal styles. Finally, the GAD group reported greater difficulty remembering their childhood. Whether the latter reflects motivated cognitive avoidance of negative memories or the fact that GAD clients have a harder time remembering anything due to the sheer amount of conceptual activity in which they are constantly engaging is not yet known.

6.19.4.3.2 GAD and adult interpersonal factors

Clinicians often discover that many of the concerns raised by their GAD clients relate to interpersonal relationships. Research at the Pennsylvania State Project (Pincus & Borkovec, 1994) has made use of the Inventory of Interpersonal Problems Circumplex Scales (IIP-C, Alden, Wiggins, & Pincus, 1990) to assess the interpersonal functioning of GAD clients in a psychometrically sound way. Results indicate that GAD clients show not only greater interpersonal distress (not surprisingly) but also a greater rigidity in their interpersonal styles across differing situations than nonanxious people (Pincus & Borkovec, 1994). Thus, GAD has now been shown to reflect inflexibility in cognitive, affective, central physiological, peripheral physiological, and interpersonal behavioral domains. More importantly, cluster analysis has revealed three subtypes of GAD, replicated in both initial and cross-validation samples. The first of the two smaller clusters (24.3% of the clients) involved social avoidance and nonassertiveness, whereas the second cluster (13.5%) was characterized by elevated domineering and vindictive scales. The primary interpersonal problems for GAD (62.1% of the clients) were found on the overly nurturant and intrusive scales. Relating this to the attachment results, the majority of GAD clients may have learned in childhood to care for others in order to get love, approval, and nurturance, and they may continue to repeat this pattern in adulthood for the same reason. Worry may thus function, as it did in childhood, as a means of anticipating the needs of, and threats to, significant others in the pursuit of satisfying interpersonal needs. The discovery of this majority cluster, along with the attachment results, also fits well with research (Peasley, Molina, & Borkovec, 1994) showing that GAD groups report higher degrees of empathy on the Interpersonal Reactivity Index (Davis, 1980). This empathy was most prevalent in the realm of feeling other people's pain. Thus, attempts by GAD clients in the overly nurturant cluster to take care of others may also be motivated by attempts to reduce one's own pain caused by intensely feeling the pain of others.

6.19.5 THERAPY OUTCOME INVESTIGATIONS OF GAD

Although the findings on the possible role of interpersonal factors in GAD suggest that such factors may become a very important feature in the future development of more effective therapies, all controlled therapy outcome investigations to date have involved evaluations of behavioral and cognitive-behavioral therapy (CBT) treatments that target intrapersonal anxiety process.

6.19.5.1 Review of Past Controlled Therapy Outcome Studies of GAD

Systematic development and evaluation of psychotherapies for GAD began only recently for two reasons. First, GAD has historically been an ambiguous disorder with frequent changes in diagnostic definition. Second, the etiology of GAD was not well explained by the discrete conditioning events that have been used to elucidate the origins of other anxiety disorders. Moreover, because conditioned environmental triggers for anxiety were not obvious, and internal cues were more functionally relevant, the utility of exposure methods was less clear for the diffuse forms of anxiety found in GAD. Thus, early treatments for GAD emphasized the somatic aspects of the client's anxiety and trained clients to use relaxation techniques as a general coping response whenever they felt anxious. Later developments involved the addition of elements from behavioral self-control and cognitive treatments. These elements included an emphasis on thorough applied relaxation training (Öst, 1987), rehearsal of relaxation and cognitive coping responses during imaginal exposures to environmental and internal fear cues (e.g., self-control desensitization (Goldfried, 1971), anxiety management training (Suinn & Richardson, 1971), and CT aimed at modifying the GAD client's constant perception of threat (Beck & Emery, 1985). The emerging view of GAD, based on growing evidence concerning its nature and the specific functions of worry, now sees it as a loosely structured cognitive-affective state (Barlow, 1988) whose process is characterized by spiraling, habitual, inflexible interactions of multiple systems responding to constantly perceived threat (Borkovec & Inz, 1990). Thus, intrapersonally focused CBT was designed to provide multiple coping responses for the targeting of each of the maladaptive reactions and their interactions and to replace anxiety-maintaining spirals among these systems with alternative responses. Such a treatment should be able to help an individual to develop a flexible, adaptive lifestyle conducive to reduced anxious experience.

Only 12 controlled outcome studies on *DSM*-defined GAD have been published. Review of 11 of these studies indicated that indeed CBT produces both statistically and clinically significant change, with maintained or increased improvement up to a year later (Borkovec & Whisman, 1996). This therapy has also been associated with low drop-out rates, declining use of psychotropic medication, and the largest degrees of change among contrasted therapies and control conditions on both anxiety and depression measures. Fifteen earlier outcome studies of "general anxiety" are consistent with the GAD trials: anxiety management has produced long-lasting gains that were sometimes superior to component conditions, and CT techniques may add to post-therapy and especially follow-up improvement (Durham & Turvey, 1987; Lindsay, Gamsu, McLaughlin, Hood, & Espie, 1987). Finally, a twelfth GAD study found CBT to be superior to anxiety management at six-month follow-up and superior to brief psychodynamic therapy at post-therapy and follow-up (Durham et al., 1994). However, several methodological flaws render the conclusions questionable (brief duration of GAD, therapist-by-treatment confound, lower credibility for the psychodynamic condition, no therapy manuals, large drop-out rate, higher severity for the psychodynamic condition, and no therapy integrity checks).

Despite these promising effects, three areas of concern exist (Borkovec & Whisman, 1996). First, the role of nonspecific factors or individual CBT components remained unclear until the late 1990s. Although placebo and individual elements have yielded less change than CBT, between-group effects have not always emerged. Second, clinically significant change for CBT has been moderate at best (50% high endstate functioning on average across studies). An earlier review of nine of these studies came to similar conclusions (Chambless & Gillis, 1993). Finally, although their methodology has been fairly good (e.g., frequent use of manuals, diagnostic interviews, integrity checks, and expectancy/credibility assessments), significant deficiencies exist in the majority of the studies. Most importantly, only three studies required two independent diagnostic interviews. Principal GAD has the lowest interassessor kappa among anxiety disorders (Barlow & DiNardo, 1991). Absence of independent diagnosis raises the possibility of false-positive cases (as many as 25–30%). Increased error variance due to false-positive cases may explain why CBT has not always produced significantly greater improvement than nonspecific or component conditions and why prior basic research on GAD has often yielded ambiguous or conflicting results.

Somewhat greater clarity on the issue of nonspecific effects and the contribution of individual CBT elements was achieved in a comparison of applied relaxation, CBT (applied relaxation, self-control desensitization, and brief CT), and a reflective listening control condition (Borkovec & Costello, 1993). Unlike many prior studies, this study required two independent diagnostic interviews, as well as quality and adherence checks of the therapy provided. At post-therapy, applied relaxation and CBT were superior to reflective listening, despite the fact that reflective listening was superior to the other two conditions on depth of emotional processing as objectively measured by the Experiencing Scale (Klein, Mathieu-Coughlan, & Kiesler, 1986). However, at 12-month follow-up, clients in the reflective listening condition had lost most of their gains and had more frequent subsequent therapy, clients in applied relaxation had maintained their gains, and those in the CBT condition showed further gains and had higher endstate functioning (50% of the clients) compared to the other two conditions. These findings support the view that a cognitive behavioral treatment for a multidimensional disorder like GAD will be most effective if it targets each (cognitive, physiological, and imaginal) system found in basic research to play a significant role in GAD.

The fact that reflective listening produced greater levels of emotional processing but failed to achieve a better outcome in the above trial suggests that the type of emotional processing that occurred was not therapeutically relevant to this disorder. From an experiential perspective, the primary affects most centrally involved in emotional disturbance are not easily accessed in GAD when reflective listening alone is provided; the avoidant function of worry may yield a client focus on secondary or instrumental affect (Greenberg & Safran, 1987). For emotional processing to occur, more potent techniques for accessing and deeply experiencing underlying, primary emotions in the present moment may be necessary. But the development of such a therapeutic focus, either for exposure treatment or for experiential techniques, must await future research which identifies what those primary fears might be in GAD.

The current therapy study in the Pennsylvania State Project compares applied relaxation/self-control desensitization, CT, and their combination. Therapy time was increased by 50% to allow for more complete CT than in the previous trial. Preliminary results based on a partial sample have indicated that one-third of the clients in each of the three conditions reached high endstate functioning by the end of therapy. At both follow-ups, however, the combined CBT group had increased to a 50% rate, whereas the two single-element conditions lost endstate gains. Should these outcomes hold up once all clients have completed therapy, they will support the already existing trend in the outcome literature suggesting that long-term maintenance is indeed best produced by a combined CBT therapy that targets each of the intrapersonal anxiety response systems. However, it is also clear that the attempt to increase the efficacy of CBT by doubling therapy time was not successful. CBT outcome at follow-up was not significantly different from previous trials. This strongly suggests the wisdom of looking elsewhere to develop more powerful therapeutic approaches for GAD. Further preliminary results from this ongoing trial strongly suggest that this may well involve the therapeutic targeting of interpersonal problems (Borkovec, 1995). Three of the IIP-C scales that significantly contributed to the clustering results (domineering, overly nurturant, and intrusive) failed to change significantly after CBT. Most importantly, these three scales (plus the vindictive scale) negatively predicted outcome, and these relationships were stronger at follow-up than at post-test. Thus, interpersonal problems, if left unattended in therapy, may be especially associated with failure to maintain therapeutic gains obtained by intrapersonally oriented CBT.

6.19.6 CLINICAL DESCRIPTION OF COGNITIVE-BEHAVIORAL THERAPY FOR GAD

Despite limitations in CBT, both in degree of improvement and failure to address potentially important interpersonal issues, it is the only therapy method for GAD which has been empirically validated (Chambless et al., 1996). This section will provide a clinical description of the CBT elements which are most frequently used in controlled trials with the disorder. The protocol treatments in these trials have depended on such basic resources as Beck and Emery's (1985) text on CT with anxiety disorders and Bernstein and Borkovec's (1973) manual on progressive relaxation training. The principles and techniques of those approaches will not be reviewed here in detail. Instead, the present section will describe clinical adaptations of basic behavioral and cognitive therapy methods specifically for GAD, adaptations which have often been guided by the basic empirical research on the disorder summarized earlier in this chapter.

6.19.6.1 Self-monitoring and Early Cue Detection

Self-monitoring of anxiety cues on a moment-to-moment basis is foundational to CBT with GAD. Although the identification of environmental cues is important, greater emphasis is placed on determining relevant internal cues that trigger anxiety and worry. The latter include attention, thoughts, images, bodily sensations (especially muscle tension), emotions, and behaviors. Human experience is described to the client as an active process involving the interaction of these internal cues as they respond to a constantly changing environment. Anxiety is the result of an incremental process that develops as each internal cue is triggered by other cues in a combined effort to respond to perceived threat.

For example, a person has a thought, which triggers an emotion, and that emotion triggers another thought which triggers muscle tension, which leads to the spiraling up of anxiety. It is not our reactions to events that are the problem; the initial reaction is quite natural and understandable, given our past history of learning. The problem resides in our reactions to our reactions. These are the habits which we have developed and that are further strengthened each time we allow their entire sequence to occur. In therapy, the deliberate changing of reactions to our reactions and the strengthening of new coping responses in each relevant system are targeted. Emphasis is therefore placed on increasingly early detection of internal changes occurring in an anxious direction. The earlier we can identify incipient cues for anxiety, the earlier we can intervene. Any new intervention will be more effective in reducing anxiety if it is applied earlier in the spiral.

Asking clients to describe typical anxiety experiences in terms of what they attend to, do, think, imagine, and somatically and emotionally feel is a good starting point. However, the use of imagery of past or upcoming anxiety-provoking situations can help clients more accurately identify the internal contents and sequences of actual anxious experience. The use of a repeated image can help clients attend to each relevant system and to practice the early detection of relevant cues. This in-session exercise also provides a concrete rehearsal of the very self-monitoring that clients are asked to practice in daily life. Of particular importance is the actual worry process. Asking clients to worry silently about a typical topic of concern allows them to observe and describe this process in a more objective way. Asking them to subsequently worry out loud is often useful as well. This exercise gives the therapist some hints about what the nature and content of worry are for a specific client.

The therapist also observes clients for any detectable shift in their affective state and immediately asks them to describe what is occurring. In this way, the therapist serves the role of early detector of incipient anxious spirals and facilitates client recognition of early cues. Clients are encouraged to tell the therapist when they notice the beginning of anxiety cues. Such encouragement allows the therapist to fade out prompting as clients rehearse their own early detection, the very goal of self-monitoring in daily life.

Clients are encouraged to practice self-monitoring on a daily basis between sessions. Remembering to do so is the most difficult challenge, so the therapist provides a variety of suggestions for establishing reminders in the client's environment (e.g., checking every half-hour, at every change in activity, and in response to noticing post-it notes placed in noticeable locations). Over time, increasingly specific reminder cues which are particularly suited to the anxiety process of individual clients can be identified and used (e.g., whenever the phone rings, whenever a particular co-worker or family member is first seen during the day, whenever the client notices foot-tapping or hair-twisting behaviors). The important thing is that a sufficient number of effective cues are established to frequently remind clients to observe their inner processes. The ultimate goals are to establish a habit of recognizing incipient anxiety and to intervene at that moment with whatever coping responses have been learned up to that point.

Self-monitoring need not be focused only on anxiety cues. Both worry in general and GAD in particular are associated with other important emotional experiences (e.g., anger, frustration, depression) as well. Learning to detect the incipient cues for each of these emotional experiences and to distinguish them from anxiety will facilitate the application and mastery of interventions better suited to them and/or may lead to the identification of their functional role as the beginning point or consequence of an anxiety spiral.

6.19.6.2 Stimulus Control Methods

Because it occurs in numerous situations, the worry process is usually under poor discriminative control. However, once clients have learned to detect the occurrence of worry, the therapist can introduce a very simple stimulus control method for reducing the amount of time spent worrying. A degree of stimulus control can be re-established by providing clients with five instructions.

(i) Establish a 30-minute worry period to occur at the same time each day and in the same place (a place not associated with other daily activities).

(ii) Learn to detect the worrying at earlier and earlier moments, with the goal to ultimately identify its onset.

(iii) As soon as it is detected, postpone it to your worry period. Remember that you will have plenty of time to focus on your worry at that time and there is no need to make yourself miserable by worrying now when you have better things to do. Also keep in mind that short-circuiting worry will help reduce its habit strength.

(iv) After postponing the worry, focus your attention on the present environment or the task at hand.

(v) Use your worry period to worry intensely or (later in therapy) to employ some of the CT strategies to eliminate the source of the worrying.

Although empirical support for the efficacy of this technique is available on college samples of chronic worriers (Borkovec, Wilkinson, Folensbee, & Lerman, 1983c), a full clinical trial to evaluate its usefulness in GAD samples has not yet been conducted. Clinical experience suggests, however, that this simple method can often provide some beginning relief fairly quickly.

6.19.6.3 Relaxation Methods

Because autonomic inflexibility is characteristic of GAD physiological process, training in multiple relaxation methods for flexible application as well as to strengthen parasympathetic tone is desirable. Such relaxation methods can include paced diaphragmatic breathing, progressive muscle relaxation, guided imagery, meditation, and, most importantly, daily application of applied relaxation. Clients are encouraged to experiment with the different techniques in response to different response system reactions and to identity which ones are most helpful under which circumstances. With several coping responses available, the likelihood of finding an effective one in any given situation increases, and clients develop an increased sense of choice and flexibility as well.

When new cognitive or behavioral techniques are introduced in therapy, it is helpful to do demonstrations wherein the clients' own deployment of strategies produces an immediate, noticeable, and positive effect, however slight. In this way, clients obtain a sense that the technique can make a difference for them with further practice and application. Slowed, paced, diaphragmatic breathing produces a rapid relaxation response with little training and can be immediately used in daily living. The therapist models and has clients imitate both rapid, shallow, thoracic breathing (a sympathetic elicitor) and slowed diaphragm breathing (a parasympathetic elicitor). In this way, clients learn that the way that they breathe affects how they feel and that they can exert some immediate control on physiological and psychological states merely by controlling respiration. Typical instructions for diaphragmatic breathing would be: "Shift to breathing from your stomach rather than from your chest. Allow your diaphragm to rise and fall without expanding your chest. Also, slow your breathing down to a rate slower than usual but not so slow that it is unpleasant or uncomfortable. You might do this by counting from one to three as you breathe in evenly and then again as you evenly exhale." A few minutes of diaphragmatic breathing practice helps clients learn what relaxation feels like and how to elicit it quickly. They are encouraged to shift to this type of breathing whenever they notice thoracic breathing in order to develop diaphragm breathing as a habit. This coping response can also be used upon early cue detection during daily self-monitoring as an initial method for learning to control anxiety spirals. Moreover, when the therapist cues the client to become aware of increased anxiety during the session, the therapist can ask them to apply this relaxation response for a brief moment to reduce those cues, thus giving clients immediate opportunities for rehearsing applied relaxation.

Training in progressive muscle relaxation (PMR) involves systematically tensing and releasing various muscle groups throughout the body. This exercise causes a lengthening of muscle fibers which results directly in reduced muscular tension and indirectly in reduced sympathetic activity. Clients formally practice the technique twice a day to deepen their relaxation response and to strengthen their ability to generate it in daily applications. As therapy progresses, muscle groups are combined, and tension production is eventually replaced by relaxation-by-recall, wherein clients merely identify extant muscle tension and let go of that tension by recalling how those muscles felt when tension was produced and released.

The notion of "letting go" of muscular tension is inherent in PMR. Each time clients let go of tension in a particular muscle group, they become a little more relaxed. Once clients are accustomed to producing relaxation by concretely releasing muscular tension, the therapist can introduce the analogous notion of letting go of other processes involved in their anxiety spirals. For example, clients can also practice the gentle letting-go of distressing thoughts, worries, images, bodily sensations, and negative emotional experiences. They can be reminded that it is their reactions to their reactions that make a difference.

Meditational techniques are often useful because they specifically emphasize attention to a single focusing device. Strengthening one's ability to shift attention away from anxiety-provoking cognitions to one pleasant, internal stimulus is particularly helpful for GAD clients whose mental life is often consumed with attention to worrisome thoughts and catastrophic images. The therapist can ask clients to use diaphragmatic breathing for this purpose, or they can work with the client to identify a specific image or word which taps into previous senses of safety, comfort, security, love, and/or tranquillity. The word, "home," for example, for some clients may be associated with special, positive meaning. For other clients, interpersonal connections (e.g., an image of one's infant daughter) might serve this purpose. Clients are asked to practice meditational methods by focusing on the pleasant internal stimulus for a few moments at the end of formal PMR practice and to incorporate the use of this technique into their daily relaxation applications.

Guided imagery can also be introduced by selecting scenes which are associated with tranquillity and pleasantness. Scenes can be constructed such that they sequentially produce deeper states of relaxation and varying types of additional positive affect. Although guided imagery is not useful for the rapid elicitation of a relaxation response during early cue detection, it is a helpful device for deepening relaxation during formal practice sessions or at other moments in the day when a relaxation break is taken in order to reduce built-up anxiety and tension.

Many GAD clients are perfectionistic, with high performance standards for themselves and fear of the judgments of others. Consequently, attempting to achieve a completely relaxed state may, in itself, generate anxiety which may interfere with that very goal. The therapist can describe relaxation training in terms of "movement toward relaxation." Applied relaxation is merely a matter of shifting the direction of the internal process away from a spiral of tension and anxiety; the movement toward relaxation process, no matter how slight, is one of the most useful directions because of its direct incompatibility with anxiety. Frequency of application is more important than depth of relaxation. Other than movement toward relaxation, there is no end-state being sought either during training and practice or in application.

Perfectionism is only one example of a basis for relaxation-induced anxiety (RIA), a phenomenon common among diffusely anxious individuals. Other possible reasons include the potentially frightening nature of unfamiliar cognitive or physiological activity elicited by relaxation, fear of losing control, and increased awareness of feelings of anxiety or other emotions (Heide & Borkovec, 1984). If the very method for reducing anxiety is itself anxiety-provoking, the likelihood of a therapeutic effect in its application is minimal. Indeed, in the three published GAD therapy investigations which measured the occurrence of RIA during training, the degree of its occurrence negatively predicted outcome (Borkovec & Costello, 1993; Borkovec & Mathews, 1988; Borkovec et al., 1987). Fortunately, methods exist for circumventing this problem. Stressing the notion of movement toward relaxation is one. Another is to teach an alternate relaxation technique; clients who experience RIA with one type of relaxation tend not experience it with another (Heide & Borkovec, 1983). Moreover, when the emphasis is on frequent applications of brief relaxation responses to detected anxiety cues rather than on twice-a-day formal practice of deep relaxation, there is less likelihood that clients will experience RIA. Finally, treatment of RIA in more difficult cases is analogous to exposure treatment of any feared event: training can be systematically conducted in a graduated fashion, with exposures to increasingly deeper levels of relaxation over sessions. In our current therapy trial using these methods, the correlation between in-session RIA and therapeutic improvement is no longer significant.

One of the overarching goals of relaxation training and application with GAD clients is to increase the amount of time spent focusing on the present moment rather than on anxiety-provoking thoughts and images about the future or the past. Early sessions devoted to the identification of internal triggers to the anxiety spiral have already demonstrated to clients that what they are thinking and imagining contributes significantly to their anxiety; they are partly creating their realities. The next step is to discuss the fact that, when we are thinking about the future or the past, we are creating an illusion. These future and past events do not exist now. But we still react emotionally as if they are actually occurring. Images are particularly powerful elicitors of this effect; they can cause nearly the same degree of physiological reactivity which the occurrence of the real events they reflect would cause. So we produce much of our anxious experience merely by thinking worrisome thoughts and imagining catastrophic scenes. A second disadvantage exists when clients pay excessive attention to the future or the past. As long as they are not paying attention to the immediate environment, they are not processing further information from the actual world; there can be little learning and development in their knowledge and adaptive behavior. The therapeutic implications of this are clear: the more time clients spend focused on what is real and in front of them, the less time they spend creating negative emotional experience and the more time they spend processing adaptive information. Consequently, the therapist works with clients during sessions to practice focusing attention on what is actually present. Initially, with eyes closed, clients are asked merely to attend to sounds occurring in the environment, the tactile feelings of the chair, and the odors in the air. They are instructed to return their attention to these sensations whenever they notice their attention drifting to other thoughts or images and to sense them without making judgments or elaborating on their further meaning or associations (i.e., no reactions to reactions). The same exercise is then repeated with eyes open, and later as they walk around the office. They are finally encouraged to increasingly practice shifting to this kind of focus throughout the day and to let the therapist know in the next session what new sensations they have discovered across multiple situations.

As clients report that relaxation applications are beginning to have some noticeable effects, they are further encouraged to begin noticing what emerges from states of greater tranquillity. We know from decades of research that anxiety interferes with many adaptive processes and that relaxation facilitates many forms of performance. The inverted-U nature of arousal effects on performance can be described to clients (i.e., anxiety at moderate levels is optimal but can interfere with performance at very low and high levels), and they are asked to begin observing what adaptive behaviors become disinhibited or facilitated when they are creating greater states of relaxation for themselves. These may include more effective interpersonal behaviors, greater clarity or logic in thought, or better efficiency and productivity in work. They are thus invited to explore and discover on their own what benefits relaxation may yield. Behavioral experiments are often useful devices for demonstrating such effects. For example, clients can conduct an ABAB experiment at work, where "A" represents their usual state during work and "B" represents work done in a more relaxed state. Emotional state as well as productivity, accuracy, or efficiency can be dependent measures for them to assess the impact of relaxation on their work.

6.19.6.4 Applied Relaxation

Merely training clients in a relaxation technique and asking them to practice it twice a day are unlikely to yield significant benefits. It is surprising that before the mid-1980s, many therapy trials which included relaxation methods provided only these elements. Twice-a-day formal practicing is designed to provide momentary breaks to return oneself to a more tranquil state and to further build the skill of eliciting relaxation responses and of identifying what relaxation feels like so that the clients know what it is that they can usefully move toward. But the real potency of relaxation resides in its deployment on a moment-to-moment basis whenever incipient anxiety spirals are detected. Although clinical applications of relaxation had certainly been grounded more thoroughly in the importance of daily applications, it was not until Öst's article on applied relaxation (AR) that clinically thorough relaxation training was incorporated into therapy research (Öst, 1987). Evidence has now accrued to indicate that this technique by itself can be a potent coping strategy for several anxiety disorders.

The essential feature of AR is the frequent elicitation of relaxation in response to anxiety and tension triggers. With GAD clients, this would include worrying. The therapist has already laid the essential foundation of AR in first-session work with clients on early cue detection and the use of diaphragmatic breathing as a rapid coping response to detected cues. Rehearsals of AR take place in the session whenever the therapist suggests a brief application of relaxation in response to observed signs of increased anxiety. Differential relaxation training is also conducted to facilitate the generalization of relaxation skills to daily living. Clients are taught to relax themselves not merely when reclining in a comfortable chair but even when sitting in upright chairs, walking, and engaging in various common activities. The therapist tells clients that unneeded muscular tension comes in two forms: excessive tension in muscle groups required for an activity (e.g., neck muscles needed for holding the head erect) and any tension in muscles that are unnecessary for an activity. The goal of differential relaxation is to identify when either excessive or unnecessary tension exists and to let go of that tension while continuing to carry out the activity. In-session practice involves engaging in commonly performed activities while identifying and relaxing away excessive tension, and between-session practice is encouraged to adopt a more habitually relaxed lifestyle. Cue-controlled relaxation is often instituted wherein a particular word (e.g., "relax," "calm," or a word taken from meditational focusing devices) is paired with the release of muscle tension during PMR and then used as an initial response to initiate applied relaxation in daily coping.

Clients can also be encouraged to use the relaxation response as a method of opening up to experience. From a more tranquil center established via relaxation, they are asked to shift their attention more completely and frequently to the world around them, taking in the information which it provides and allowing stressful stimuli merely to "pass through" them without reacting to such events.

Finally, clients are told that when stressful events are upcoming, they can think in terms of three phases during which they can apply their relaxation coping responses: in anticipation of the event, during the event, and in recovery after the event. It is of course useful to deploy their coping strategies throughout these phases. But often, especially in the early stages of therapy, the most noticeable effect of relaxation applications occurs during recovery. It is helpful for clients to realize that more quickly recovering from an anxious experience is a desirable event for increasing their sense of self-control and as a starting point for more effectively reducing anxiety earlier and earlier in its sequence. As skill in applying relaxation to daily events increases, the therapist and clients can begin to create behavioral homework assignments that gradually increase their exposure to stressful, anxiety-provoking situations in which to apply the methods during these three phases.

6.19.6.5 Self-control Desensitization

Because worrying prevents emotional processing and imagery can be an effective method for engaging such processing, imagery exposure techniques could be very useful in the treatment of GAD. The problem is that we do not yet know what the core fears of GAD clients are. They are anxious about many situations, therefore either *in vivo* or imagery exposure to relevant fear-evoking stimuli would be a daunting, potentially excessive therapeutic task. Until the central fears and the images that effectively access those fears can be identified by future research, self-control desensitization (SCD) is a helpful intervention tool. SCD was originally designed to deal with more diffuse anxiety problems for which discrete, graduated hierarchies of circumscribed phobic stimuli were not possible (Goldfried, 1971). In SCD, clients first focus on relaxation process until they have achieved a relaxed state. Next, the therapist asks the clients to imagine themselves in a situation where internal and/or external anxiety cues occur. Clients signal as soon as actual anxious experience is elicited by the imagery, and the therapist then has them imagine coping effectively with the imagined situation by using the relaxation response. Clients signal again as soon as they no longer notice anxious responding, and they continue to imagine themselves in the original situation but effectively coping with it. Finally, images are terminated altogether, and clients return to focusing only on the relaxation process. The goal of SCD is to have the client rehearse relaxation applications to the kinds of situations that they often find problematic. Some degree of extinction process may take place, but the usefulness of the method probably resides more in the strengthening of adaptive coping responses to typical fear cues. Thus, clients are more likely to remember to employ coping responses during daily living given associative priming effects from previous imaginal rehearsals in therapy.

"Hierarchy" construction for SCD is less detailed than it is in systematic desensitization. The therapist helps clients identify both the internal cues of their anxiety spirals (somatic, cognitive (especially worry and catastrophic images), and behavioral) and representative types of external situations where anxiety and worry often occur. Images that include both internal and external cues are constructed for use during SCD and only roughly graded from mild to moderate to severe in anxiety-provoking value. The paragraph below exemplifies one possible method for conducting a formal SCD procedure with such images once the client is in a deeply relaxed state. It includes both therapist patter and procedural instructions.

> I will now begin to present the images which we discussed earlier. Remember to visualize yourself as if you are actually in the situation as realistically as you can. Also, be sure to raise your index finger immediately when you first notice the beginnings of any tension, anxiety, or shift away from the feelings of deep relaxation. Once you have signaled, be sure to become fully aware of what the feelings are like, continue to imagine the scene that I am describing, and hold your finger raised until you notice that the anxiety feelings are disappearing ... Visualize yourself at work at your desk with the boss nearby ... Imagine that your mind is thinking, "what if I make a mistake?" ... What if I should do something foolish? ... You can feel the anxiety beginning to increase as your mind is thinking these things ... The tension and anxiety are rising as your mind continues to worry about acting foolishly ... Imagine that your heart is beginning to pound ... More and more quickly and intensely ...

When the client signals anxiety, or after 60 seconds of visualization without a signal, introduce the coping statements:

> Just continue to imagine yourself at work at your desk with the boss nearby but now imagine yourself relaxing ... Just visualize yourself relaxing away the tension and anxiety, letting go of the worries ... and as you do, imagine that the relaxation is reducing the speed of your heart, the tension in your muscles ... Calm and peaceful ... quiet and relaxed ... Muscles becoming more and more deeply and more completely relaxed ... Heart-racing just melting away, dissipating ... Breathing becoming more and more smooth and regular ... As you imagine yourself at work with the boss nearby and relaxing more and more ... Just letting go of the tension and anxiety and worrisome thoughts and focusing on your work ...

Continue such patter for another 20 seconds if there is no client signal, then terminate the image and use periodic relaxation patter to deepen the relaxed state for 20 seconds. If there is a client signal, continue with the above patter (eliminating references to the anxiety cues) for another 20 seconds beyond the point where the anxiety signal is dropped:

> Just continue imagining yourself at work with the boss nearby ... Relaxing more and more deeply ... Muscles continuing to smooth out and unwind ... Loosening up and becoming more and more comfortably and deeply relaxed ... Nothing to do but to enjoy the pleasant sensations of relaxation as the relaxation process continues to take place as you imagine yourself peacefully at the office focusing on your work.

Then instruct the client to stop visualizing that scene and to continue focusing on the relaxation for another 20 seconds:

> Stop visualizing that scene and go on relaxing ... Allowing the relaxation process to continue to take place now ... Calm and quiet ... Peaceful and relaxed ... Simply enjoy the pleasant feelings of relaxation and notice how very good it feels to be so deeply and completely relaxed.

Repeat each image a minimum of three times, or, if anxiety was signaled, until the client twice consecutively no longer signals anxiety within 60 seconds or until the client is able to terminate the anxiety fairly quickly (e.g., drops signal within seven seconds).

Over time, the therapist introduces more anxiety cues into the images. Ultimately, the client should be able to imagine all cues typical of their anxiety experience, either without reacting with anxiety or being able to rapidly terminate the anxiety. Varied environmental contexts which incorporate the client's typical anxiety-provoking situations can be used in the imagery scenes. Not every cue will have a chance to be paired with every environmental context. It is ideal to avoid over-repetition of any one context and to cover a representative sampling of contexts and at the same time provide a complete coverage of the kinds of internal anxiety cues typically experienced by the client.

Once formal SCD has been initiated in therapy, clients are asked to use the technique at the end of their own daily relaxation practice sessions. The client begins by repeatedly employing the same image that was introduced in the last therapy session. This image should be used until it no longer elicits anxiety, at which time another image that represents the kinds of anxious experience that they have during the week can be substituted.

As therapy progresses, the therapist can also employ an informal variant of SCD: whenever clients begin discussing upcoming stressful events or current worries, the therapist can, with or without first eliciting a relaxation response, ask them to close their eyes and engage in an SCD presentation involving these situations or worries. For worries in particular, the therapist can merely ask the client to begin worrying, and, once it is established, to let it go and relax. Finally, toward the end of therapy, formal SCD can be done in two additional ways that mimic real life events to a closer degree. One involves sequentially presenting several different images representing a variety of different stressful events or circumstances without the client planning these images beforehand and with only a single presentation of each image. Thus, an element of surprise typical of naturally occurring events can be incorporated into imaginal rehearsals. The other method is to present unplanned images that form a seamless story that is both typical of the client's daily experiences with anxiety and represents a building accumulation of stressful events. During both methods, the client's task is merely to engage in ongoing coping in the usual imaginal way as previously done, but without breaks in the scene presentations.

Once CT (discussed below) has been initiated, self-statements that are anxiety-reducing for a particular client can be added to their repertoire of coping responses during SCD imaginal exposures. Thus, the client is encouraged to use both relaxation responses and perspective shifts to more accurate ways of thinking about the represented situation as means of coping with the anxiety and worry elicited by the scenes.

6.19.6.6 Cognitive Therapy

Basic CT for anxiety disorders (Beck & Emery, 1985) involves a fairly straightforward series of steps which can be summarized by a set of questions that the therapist can ask the client:

(i) How are you perceiving the situation (what are you thinking, imagining, predicting, saying to yourself, interpreting, believing)?

(ii) Is this way of perceiving accurate (what is the evidence)?

(iii) If this way may not be true, what alternative ways are there to see the situation that have evidence for being more or equally accurate?

(iv) Whenever you notice yourself using the old way, why not try viewing the situation with one of the alternatives which may be more true, or try testing out the perspectives by conducting experiments during your daily life to get the evidence you need?

In initial sessions, the therapist already helped clients identify the variety of internal cues associated with their anxiety and worry, including thoughts and images, to notice what immediate effect these cognitions can have, and to notice that their minds and bodies are reacting to something that is not now present and does not exist in the present. Clients are encouraged to view cognitive events as hypotheses rather than as facts, as predictions which may come true in the future. They are asked to estimate the probability that their feared outcome will actually happen. This question is linked to the idea that it is wise for them to avoid only probable dangers rather than every conceivable outcome. If the danger does not have a high likelihood of occurrence, there may be more accurate predictions available. If the danger does have a high likelihood, the client is asked to rate how well he or she could cope with the feared outcome. This question is linked with the idea that we often underestimate our ability to cope with predicted negative events.

When analyzing the truth-value of particular perspectives, clients are asked to consider the advantages and disadvantages of this way of seeing things and to examine the evidence for it. Quite often, very few advantages can be identified, and the anxiety and worry that follow from it are obvious to the client. The probability of something happening in the future is often best estimated by how frequently it has happened in the past, and the therapist and client can search personal history to come up with a meaningful estimate of the chances for the occurrence of the feared event. In addition, statistics are sometimes available to specify the likelihood of some negative events.

Although such traditional methods of helping clients logically analyze the likelihood that their perspectives are accurate or inaccurate are useful, the most important therapeutic task involves learning to observe the environment on a daily basis, fully processing the new information that is available, and using this information to construct new models of the way things actually are. GAD clients have two characteristic tendencies which ordinarily counteract such a process: focusing on mental illusions of the past and the future and excessively attending to the negative features of environmental information. Therapists therefore encourage them to become more objective in their view of events, distinguishing what is actually and descriptively occurring from their interpretations of events or their guesses about what the events may mean. One of the best ways of helping them with these tendencies with regard to their worrying involves daily monitoring of worry content and the specific predictions they are making and then observing the actual outcomes which eventually occur. As mentioned earlier, when an outcome relevant to a worry does occur, they rate how bad the outcome was and how well they coped with it. They are asked to think carefully about each actual outcome and what it might mean for revising their models of the way things are. By using the worry outcome monitoring method, clients create their own new history of events, more objectively considered, upon which to base predictions about the future and ways of seeing themselves in the world.

Because so many anxieties and worries relate to social evaluative situations, distancing methods are often initially useful, wherein clients are asked to logically analyze the thoughts and predictions of another person rather than of themselves (e.g., a friend or acquaintance, a hypothetical stranger, or the therapist role-playing someone else). Such distancing reduces the likelihood of the clients' habitual fear and avoidance responses to such material and allows them to think more clearly and to reason more accurately.

As clients engage in logical analysis and generate more accurate perspectives, they commonly report that the alternative perspective just does not feel true in the way which the old view does, even though it is more logical. There is very good reason for this. Worry contains numerous brief images of negative events, and imagery can result in bodily reactions similar in type and intensity to the actual occurrence of an event. The more one imagines catastrophes, the more real they feel. Of course images of more likely positive outcomes have been occurring far less frequently, so the "feeling" that these are true is less strong. This is one of the reasons why the cognitive products from CT are incorporated into SCD procedure and why realistic images that indicate everything turning out well can be usefully added toward the end of coping image rehearsals.

Although CT begins with specific thoughts and images, the therapist and client eventually identify recurrent, underlying themes that reflect their core beliefs and CT proceeds in a similar fashion using the core beliefs as targets for intervention. Formal assessment of characteristic thought styles can facilitate the identification of such schemata. Among the factors from the Dysfunctional Attitude Scale (Beck, Brown, Steer, & Weissman, 1991), GAD clients in the current Pennsylvania State Project score highest on items referring to fear of disapproval, dependence on others for their happiness, and excessively rigid rules about the way things "should" be. A major goal for CT with GAD, therefore, involves the creation of greater freedom from others' opinions and more flexible rules by which to judge oneself and others. Central to these is the gradual shifting of perspective from an extrinsic to an intrinsic focus. If clients can learn to attend only to the process of their actions and experiences rather than to the outcomes, less time will be spent generating anxiety-provoking cognitions about what negative things might happen, and more time is devoted to attending to the form and quality of the process of living. For example, when people are at work, they can choose to pay attention to the external rewards which may come from the work (and thus create performance anxiety due to fear of failure), or they can choose to focus on the work itself, its intrinsic meaning, or how it can be done in a beautiful, skillful, or joyful manner. Therapists can help clients to identify the specific elements of any activity or role which can be pleasing or life-affirming. Rehearsals in SCD of adopting such alternative perspectives can strengthen the tendency to employ such views on a daily basis.

Clients can have a difficult time at the beginning of CT when they are asked to generate alternative ways of thinking or believing; old habits have often been present for a long time. To facilitate flexible thinking, it is useful first to practice generating multiple perspectives on neutral topics where avoidant tendencies are less strong. For example, how many ways are there to see this pencil? What shapes can we see in the cloud formations? How many different ways do characters in situation comedies on television view the same "objective" event? Such rehearsals of flexible thinking show clients that many ways exist to perceive something and that we can create what those ways are for any situation. When the therapist eventually addresses anxiety-provoking situations, the first step is to generate several possible perspectives (even humorous ones) without initially judging their reasonableness. The second step is to choose one of the perspectives for application, using such touchstones as evaluating the advantages and disadvantages of each perspective and judging its likely accuracy based on logic, probability, and evidence.

In defining their core beliefs, GAD clients also often use words which have a strong emotional impact and which are vague enough to apply to any situation. For example, a common core belief for someone with GAD might be, "I must be perfect at everything I do or I am a failure." A helpful intervention is to ask the client to define what they mean by each word in the above phrase and to determine how realistic it is. For example, how do they determine their own perfection? Do they really need to do everything perfectly, or are there only some things which are important? Is it possible for them to be perfect at everything? Could they still be successful at something if it was not perfect? The therapist can encourage clients to reword their core beliefs so that they are much more specific. For example, instead of using the above phrase, the client might state, "I choose to be the best (mother, teacher, writer) that I can." The latter phrase is much more specific, avoids social comparison by refocusing on self-competition, focuses on the process (trying one's best) instead of the outcome, and implies choice.

A goal of CT for GAD involves the creation of more balanced perspectives, that is, the addition of realistic views to older, habitual, negative views. It is not a matter of looking at the world with rose-colored as opposed to brown glasses, but rather of using clear glasses. With a greater number of perspectives available, clients have choices rather than being determined by habit. Once more adaptive cognitions are employed with success in their daily lives, clients can be introduced to one further step: expectancy-free living. Although planning and anticipation are necessary human processes under certain circumstances, much of the time expectancies are not necessary. In fact, expectancy can distort the processing of information, influence what is recalled from memory, create negative mood states during anticipatory periods if its content involves negative predictions, and can never fully anticipate the way things will turn out anyway. Living with a focus on the present, processing information from the world as it arrives, and trusting one's ability to cope with whatever comes down the road are alternative perspectives potentially useful to practice to help the client discover under what circumstances such a lifestyle can be adaptive and enjoyable. As an anonymous poet from Crete wrote, "I fear nothing; I hope for nothing; I am free."

Because so much of the inner life of the GAD client revolves around fear of potential bad things which might happen, a perspective shift which defines "bad" in a more relativistic way can be helpful. Certainly we need to evaluate and react to events as they occur partly on the basis of our immediate judgments about "good" and "bad." But events reflect only relative and not absolute qualities. For example, the first author as a teenager spent his life savings on a used car, whose engine died two months later. This was a bad thing. However, it forced him to find a new job reachable by public transportation. The new job location was where he met his wife, the best thing that has ever happened to him. We cannot adaptively seek out bad events just because they might lead to something good. But when either bad or good events happen, it is useful to realize that new choices are made available, new doors are opened, and nothing is absolutely bad. If this is the case, then anticipations of bad events, so frequently characteristic of GAD, take on a slightly less rigid meaning.

Decatastrophizing is a useful, traditional CBT method with GAD. Given that clients frequently fear the worst, identifying what exactly that would be, the various steps which it would take to get to that point, the probability of each step, what alternative perspectives could be adopted, and what coping resources exist for each step can often significantly reduce the fear associated with the area of concern. If the probability of all steps occurring together is established to be quite low and the likelihood of inability to cope is determined to be nearly nonexistent, clients can be encouraged to consider a horse-betting analogy. Would they bet their life savings on a horse which has come in last every time in the past or on a horse which has always won? They may wish to consider how they are betting their daily emotional life in a similar context.

Behavioral experiments can be constructed for clients to conduct between sessions to test old and alternative perspectives. Such experiments often provide opportunities for graduated exposure as well. Asking clients to approach feared situations to obtain evidence for beliefs can thus serve a dual purpose. Although circumscribed anxiety-provoking situations are not as salient in GAD, clients do often engage in a variety of subtle avoidances (Butler, Cullington, Hibbert, Klimes, & Gelder, 1987). One frequent area of avoidance inherent to GAD is cognitive avoidance. For true exposure to be enacted, cognition and behavior must both reflect an approach. What perspective clients adopt during an approach behavior can make a difference to the extinction process. Fear of bees is an instructive example. Fearful people often swat at bees flying around them, an irrational, nonapproach act that increases rather than decreases the likelihood of being stung. Eliminating the swatting and sitting motionless until the bee flies away still includes avoidant behavior (a freezing response). Opening up one's palm to the bee in an invitation to land on the hand is an example of a true approach response in both cognition and behavior and is likely to facilitate extinction and changes in threatening meaning.

GAD clients are excellent "yes, but ..." debaters. They have rich associative networks which construct an elaborate view of why the world is a dangerous place and why they may not be able to cope. Although CT can be seen as a very systematic, step-by-step system for modifying cognitions, there is no need to follow those steps in textbook fashion. Indeed, overly rigid therapist pursuits can lead to arguments, frustration on the part of both therapist and client, and ruptures in the therapeutic alliance which make therapy less likely to be beneficial (Safran & Segal, 1990). The alternative is to reduce the pressure on both parties, deemphasizing the need to reach a specific outcome in any particular session. The real goal is the creation of a process designed to loosen up the client's rigid, habitual modes of thinking and to generate more flexible thinking in a gradual fashion. There are many specific techniques in CBT, and the therapist can often move smoothly among topics and techniques from moment to moment in the session. As therapists do so, they watch for a softening of the client's reactions to any one of these and pursue any openings which emerge more deeply until signs of avoidance or resistance are encountered. Such an approach keeps the therapeutic process flowing without significant obstacles and no sense of failure.

6.19.7 SUMMARY AND IMPLICATIONS FOR FUTURE THERAPY DEVELOPMENT

Basic research has revealed several interrelated features for GAD which fall into three major domains: GAD (i) involves a process (worry) which functions as cognitive avoidance to anxiety-provoking material, prevents emotional processing, and thus contributes to the maintenance of anxious meanings; (ii) has a distinctive physiology typified by autonomic inflexibility and deficiency in parasympathetic tone; and (iii) is associated with specific current interpersonal problems which may have developed partly on the basis of insecure childhood attachment. Outcome findings suggest that combined CBT is likely to be the most effective intrapersonal treatment approach for producing long-lasting change, but absolute degree of improvement remains unsatisfactory. It seems likely that something else must be added to "best available" CBT techniques to yield greater and maintained clinical improvement.

Prior theorizing about GAD has emphasized the role of habitual, nonlinear, dynamical interaction of multiple intrapersonal processes (attention, thought, imagery, affect, physiology) over time in response to constantly perceived threat. The superiority of combined CBT relative to its elements does suggest that the therapeutic targeting of all relevant systems will yield the greatest change. However, attachment and interpersonal problem results now suggest an extension of this model to include another relevant system, that is, the habitual cycles of interpersonal behavior which may also contribute to maintenance of the maladaptive anxiety process. Perceived threats are often significantly related to interpersonal situations (e.g., fears of criticism for socially avoidant clients, fears of being attacked or controlled by others for dominant-hostile clients, fears of failure to take care of others and so to obtain love and approval for overly nurturant clients). The interpersonal behaviors learned to cope with these fears can be readily seen in a functional sense as negatively reinforced avoidance of such feared interpersonal consequences and of the developmentally based anxieties which underlie those interpersonal fears.

Taken together, results and theory extension provide a rich context for understanding the nature, functions, maintenance, and origins of GAD and thereby for guiding the development of more effective treatment. They suggest that future research and therapy development would benefit from a focus on (i) identification of the specific nature of the core fears in GAD and the development of more powerful methods for the emotional processing of those fears, (ii) the creation of more impactful relaxation methods for increasing parasympathetic tone, and (iii) the pursuit of the functional role of interpersonal problems in GAD process and how best to modify these problems.

6.20.1 INTRODUCTION

Specific phobias are irrational and persistent fears of certain objects or animals. Whereas specific phobia is a relatively recent concept, descriptions of the condition to which it refers have a long tradition in medical history (Errera, 1962). For example, in his writings, Hippocrates refers to a case of a man who displayed an irrational fear of bridges. Likewise, detailed discussions of phobic symtoms can be found in the work of seventeenth or eighteenth century authors such as Descartes and Le Camus.

Since the 1960s our understanding of specific phobias has steadily increased: it is now recognized that learning mechanisms and developmental processes play a crucial role in the etiology of specific phobias; there are now strong indications that certain cognitive processes contribute to the maintenance of phobic symptoms; and we have a rather clear picture of how we should treat patients who suffer from a specific phobia. The present chapter evaluates these aspects in more detail.

6.20.2 SYMPTOMATOLOGY AND EPIDEMIOLOGY

6.20.2.1 Case Vignette

Paula, aged 24, visits a psychologist because of her intense fear of spiders. She reports that she has been afraid of spiders since early childhood. In the last few months, the spider fear has become more intense. Until recently, she lived with her parents, but at the moment she has her own apartment. She is, however, seriously considering the possibility of returning to her parents' home. The reason for this is quite simple: at her parents', she was able to call her father when she suspected that there was a spider in her bedroom. On these occasions, her father inspected the room and removed a spider. Now that she lives in her own apartment, she is unable to call upon her father because her parents live in another town, some 40 miles away. Paula is especially afraid of spiders at night. Consequently, she does not sleep very well. During the day she feels tired and finds it difficult to concentrate on her work. At home, she is constantly alert and keeps scanning the environment for spiders. Returning to her parents' home would probably mean having to give up her job as a secretary.

6.20.2.2 Symptomatology

The case vignette presented above illustrates the criteria for specific phobia that are described in detail in the *Diagnostic and statistical manual of mental disorders*, fourth edition (*DSM-IV*; American Psychiatric Association, 1994). Briefly, the *DSM-IV* stresses that specific phobia contains three crucial elements: (i) the fear is directed at a clearly discernable and circumscribed stimulus (e.g., spiders), (ii) confrontation with this stimulus elicits intense fear and avoidance behavior, and (iii) the fear is excessive and unreasonable to such a degree that it interferes with daily life.

As for the first element of the *DSM-IV* definition, survey studies have shown that some fears (e.g., fear of spiders or snakes) are far more prevalent than others (e.g., fear of electricity). Factor analyses have shown that the most prevalent fears can be grouped together in a relatively small number of distinct categories (Arrindell, Pickersgill, Merckelbach, Ardon, & Cornet, 1991; Frederikson, Annas, Fischer, & Wik, 1996). Likewise, the *DSM-IV* recognizes four types of specific phobias: animal type (e.g., spiders), natural environment type (e.g., water), situational type (e.g., enclosed spaces), and blood–injection–injury type (e.g., dental phobia).

The observation that specific phobias tend to be focused on relatively narrow and circumscribed classes of stimuli has led several authors (e.g., Menzies & Clarke, 1995; Seligman, 1971) to interpret specific phobias in evolutionary terms. Briefly, these authors suggest that the stimuli feared by phobics reflect the dangers that our prehistoric ancestors faced in their (presumed) Pleistocene savannah environment. As a result of natural selection, a readiness to acquire fear of these evolutionary relevant dangers became genetically coded. Consequently, modern man still possesses a preparedness (Seligman, 1971) or an innate tendency (Menzies & Clarke, 1995) to develop fear of spiders, snakes, or blood, for example. Although these evolutionary accounts have attracted considerable attention, other interpretations of the selectivity of fears do exist. For example, the selectivity of specific fears may be a consequence of the negative connotations that certain stimuli have in our culture (e.g., spiders are commonly seen as dirty [Davey, 1995]).

The second crucial element of specific phobias is concerned with the nature of intense fear emotions. A good framework for discussing this point is the three-systems-model proposed by Lang (1968). According to this model, emotions such as fear consist of three relatively independent components: a physiological component, a subjective component, and a behavioral component. Thus, fear is reflected in autonomic symptoms (e.g., tachycardia, increased respiration, etc.), subjective feelings of apprehension, and avoidance or escape behavior. In diagnosis or therapy outcome evaluation, it is important to measure each of these components. It should be noted that each component can be measured: the physiological component can be monitored with psychophysiological techniques (recording of heart rate, respiration, etc. [Hugdahl, 1989]), the subjective component can be quantified with specially constructed self-report questionnaires (e.g., the Spider Phobia Questionnaire; Klorman, Weerts, Hastings, Melamed, & Lang, 1974), and the behavioral component can be measured with standardized approach tasks (i.e., tasks which require a stepwise approach towards a phobic object [Öst, Salkovskis, & Hellström, 1991b]).

In passing, it should be noted that not all types of specific phobias display a comparable profile with regard to the three components. For instance, both animal phobia and blood–injection–injury phobia are accompanied by subjective reports of distress. However, whereas in animal phobia distress usually takes the form of fear, blood–injection–injury phobia is associated with strong subjective feelings of disgust and repulsion (e.g., Page, 1994). Also, confrontation with the phobic stimulus elicits sympathetic activation (e.g., tachycardia) in animal phobia, but parasympathetic activation (e.g., bradycardia) in blood–injection–injury phobia. That is, although exposure to the phobic stimulus produces heightened arousal in animal phobics, lowered arousal that may result in fainting is seen in blood–injection–injury phobia (Thyer, Himle, & Curtis, 1985).

As far as the content of subjective fear is concerned, there are also major differences between situational phobia (especially claustrophobia) and animal phobia. Subjective fear in claustrophobia is not only focused on danger, but also on anxiety expectations (e.g., fear of going crazy) and bodily sensations. The latter components are less prominent in animal phobias (Craske, Mohlman, Yi, Glover, & Valeri, 1995).

The third characteristic of specific phobias that requires some elaboration is their irrational nature. The patient suffering from, say, an intense spider phobia, readily admits that his or her fear is excessive. Nevertheless, he or she is unable to inhibit fear responses when exposed to spiders. How can one account for this failure to control fear responses? A first possibility is that, although the patient is convinced about the irrationality of the phobia when questioned in the absence of the feared stimulus, the presence of this stimulus may activate unreasonable and frightening danger expectations. There is some empirical support for this line of reasoning. For example, De Jongh, Muris, Schoenmakers, and Ter Horst (1995a) asked dental phobics to rate how much they were inclined to believe highly unrealistic dentist-related propositions. Data showed that in anticipation of dental treatment, dental phobics report various catastrophic beliefs about the dentist (e.g., dentists are often impatient), the treatment (e.g., everything will go wrong), and their own reactions (e.g., I can't control myself). Such catastrophic expectations also have been described in other types of specific phobia (e.g., Arntz, Lavy, Van den Berg, & Van Rijsoort, 1993; Thorpe & Salkovskis, 1995).

A somewhat different stance is taken by Öhman (1993). According to Öhman, phobic stimuli are analyzed by fast and subcortical information processing routines. These information processing routines provide a rough analysis of the stimulus and then initiate an immediate fear response. Consequently, even before the phobic patient becomes fully aware of the phobic stimulus, a fear response is already on its way. This might explain why phobics experience their fears as automatic and uncontrollable. Support for Öhman's (1993) hypothesis comes from a study in which it was shown that subliminal presentations of phobic slides (i.e., spiders and snakes) are sufficient to elicit autonomic responding in phobic but not in control subjects (Öhman & Soares, 1994). This finding fits well with the animal studies of LeDoux (1992). This reseacher found evidence for a subcortical fear pathway linking the thalamus with the amygdala. The thalamo–amygdala pathway is a "quick and dirty" transmission route in which the thalamus carries out a crude analysis of the sensory input and then activates the amygdala, which, in turn, generates an emotional response. According to LeDoux (1992, p. 276), this pathway has adaptive value: "the thalamo–amygdala system might be especially useful as a processing channel under conditions where rapid responses are required to threatening stimuli. In such situations, it may be more important to respond quickly than to be certain that the stimulus merits a response." Thus, one may speculate that in specific phobia, learning experiences have affected the thalamo–amygdala pathway in such a way that it is oversensitive to certain phobic cues.

6.20.2.3 Epidemiology

Epidemiological studies indicate that the lifetime and the 12-month prevalence of specific phobias are as high as 11.3% and 8.8%, respectively (Kessler et al., 1994). These data suggest that specific phobia is one of the most frequent mental disorders.

In his community study among women, Costello (1982) found that animal fears (including fear of dogs, snakes, etc.) were the most prevalent, followed by nature (e.g., heights), and mutilation (e.g., injections) fears. In effect, animal fears occurred in nearly 43% of the women. Whether these fears represent clinical phobias is not clear. Employing the *DSM-IV* criteria for specific phobias, Frederikson et al. (1996) found that situational and environmental phobias had the highest point-prevalence rate (13.2%), followed by animal phobias and blood–injection–injury phobias (7.9% and 3.0%, respectively).

Most specific phobias are diagnosed more frequently in women than in men. This is especially true for animal phobias and situational and environmental phobias, but less so for blood–injection–injury phobias (Frederikson et al., 1996). There are strong indications that this sex difference in the prevalence of specific phobias cannot be explained fully by assuming that it is more socially permissible for women to report fear than for men (Cornelius & Averill, 1983). Probably, other predisposing factors (such as sex hormones, see discussed below) play a significant role in the skewed sex distribution of fears and phobias.

With regard to the natural course of specific phobia, Wittchen (1988, p. 14) summarized the results of his longitudinal community study as follows: "The natural course of simple phobias is in the majority of cases chronic and can be characterized by the persistence of mild rather than severe symptoms of anxiety over decades. Only 16% remitted completely over the follow-up period of 7 years: thus, only very few spontaneous remissions could be observed." In passing, it should be noted that specific phobia often occur as an additional diagnosis in panic disorder and generalized anxiety disorder (De Ruiter, Rijken, Garssen, Van Schaik, & Kraaimaat, 1989).

6.20.2.4 Genetics

Several large-scale twin studies have been carried out to explore to what extent genetic factors predispose to phobic fear (e.g., Kendler, Neale, Kessler, Heath, & Eaves, 1992). Briefly, these studies have found that the genetic contribution to specific phobias is significant, though small. Moreover, the genetic factors underlying specific fears are of a general nature. That is, there is no inheritance of a specific fear, but inheritance of a general trait that predisposes to neurotic complaints. In some cases these complaints amount to a specific phobia, but in other cases the complaints take the form of social phobia, agoraphobia, and so on (Andrews, Stewart, Morris-Yates, Holt, & Henderson, 1990).

6.20.3 DEVELOPMENTAL ASPECTS

In general, specific phobias are characterized by early onset ages. For example, Öst (1987) found mean onset ages of seven and nine years for animal and blood–injury–injection phobias, respectively. An early onset is also found in natural environment phobias. For example, a considerable percentage of height-fearful subjects report that their fear has always been present (Menzies & Clarke, 1993). It should be noted, however, that situational fears such as claustrophobia differ from this pattern in that they have a later onset. For instance, Öst (1987) reported a mean onset age of 20 years for his sample of claustrophobics. Nevertheless, a substantial proportion of specific phobias begin in childhood. This finding is underlined by surveys of subclinical fears among children. In an early study of MacFarlane, Allen, and Honzik (1954), it was found that only a small minority of a large sample of children ($N = 1096$) displayed no fear reactions. A similar finding was reported by Lapouse and Monk (1959). These authors found, for example, that in 6–8 year olds, nearly 44% had a mild fear of blood. Altogether, it appears that mild to moderate fears are quite common in childhood. In this connection, there are several points that deserve comment.

First, studies evaluating specific fears in children have consistently found that girls report more fears than boys (Ollendick, Yule, & Ollier, 1991). Second, the mild fears seen in children often represent transient developmental phenomena. That is to say, childhood fears follow a predictable course (Marks, 1987). For example, Bauer (1976) found that fear of ghosts and fear of animals are common in children aged 4–8. In contrast, fear of injury is more characteristic of children aged 10–12. According to Bauer, these fluctuations in childhood fear are closely tied to cognitive development. Younger children would rely on global perception and animistic concepts in interpreting cause–effect relationships. This would explain why their fears are directed at ghosts and animals. Bauer's emphasis on cognitive development makes sense. For example, the visual cliff phenomenon (fear of heights) that typically occurs in young babies between four and nine months has long been interpreted as a prototype of a genetically based fear. However, experiments show that this phenomenon critically depends on locomotor development in infants (Bertenthal & Campos, 1984). A (social) developmental interpretation of the different onset ages of fears and phobias is also presented by Öhman (1987), who points out that animal fears typically occur during a developmental phase in which young children become more independent from their parents. From an evolutionary perspective, it may be assumed that during this phase, children are vulnerable to predators. The sensitivity of young children to phobogenic animal stimuli would therefore have survival value.

Third, fear rank orders based on what children indicate as their most feared object have demonstrated that typical topics of adult specific phobias are also very common in children. For example, snakes and spiders feature high in fear rank orders of children (Muris, Merckelbach, Meesters, & Van Lier, 1997). This suggests that the content of childhood fears resembles that of specific phobias in adults.

Fourth, although it is clear that the majority of childhood fears disappear spontaneously, there are also indications that in a subgroup of children, the specific fears persist (Ollendick, 1979). Thus, the critical question to be asked is why in some cases, specific fears appear to continue from childhood into adulthood. Part of the answer probably lies in the heritability factor associated with fear. For example, Stevenson, Batten, and Cherner (1992; p. 984) found suggestive evidence that the influence of this heritability increases with age: "as children move through adolescence this would lead to avoidance behaviour which would reinforce the fearfulness of these individuals genetically prone to fearfulness. The net effect will be an increasing significance of genetic influences over individual differences with age." Furthermore, research suggests that apart from genetic factors, three types of learning might contribute to the persistence of childhood fears, namely classical conditioning, modelling, and negative information transmission.

6.20.4 PATHWAYS TO SPECIFIC PHOBIA

6.20.4.1 Classical Conditioning

Ever since Watson and Rayner's (1920) little Albert study, researchers have tried to explain the etiology of specific phobias in terms of aversive classical conditioning. Little Albert was an infant who initially showed no fear of live animals. However, he did react with fear whenever noise was produced by stricking a steel bar with a hammer. Watson and Rayner then exposed Albert to a white rat and produced a loud noise with the hammer and steel. Albert was given six trials of white rat and noise. Eventually, little Albert reacted with crying and avoidance as soon as he was confronted with the white rat. Watson and Rayner argued that the little Albert case illustrates that phobias can be understood as the outcome of a Pavlovian or classical conditioning process. In technical terms the phobic object (e.g., a rat) is a conditioned stimulus (CS) that initially elicits no fear. An aversive event (e.g., a loud startling noise) is an unconditioned stimulus (UCS) that, by virtue of its biological characteristics, reliably induces a fear response. This fear response is therefore termed the unconditioned response (UCR). If the CS is paired with the UCS, a fear response occurs and becomes associated with the CS. Thereafter, the CS is able to elicit a full blown fear response, even in the absence of the UCS. The fear response has then become a conditioned response (CR) to the CS and, consequently, the CS has turned into a phobic object.

The basic finding of Watson and Rayner, that fear can be conditioned by pairing a neutral CS with an aversive or traumatic UCS, has been replicated many times. For example, in a study by Campbell, Sanderson, and Laverty (1964), subjects listened to a tone (CS) that was followed by an injection of scoline. This injection produced a temporary respiratory paralysis (UCS) and, consequently, intense fear (UCR). Even weeks after this single conditioning trial, subjects reacted with strong autonomic responses (CR) to isolated presentations of the tone (i.e., the tone was not followed by paralysis).

Although laboratory findings such as these illustrate that conditioning processes can, in principle, produce phobia-like fears, they do not establish that in everyday life, classical conditioning is the cause of phobias. However, there is evidence to support the notion that classical conditioning processes do operate outside the laboratory chambers. For example, Kuch, Cox, Evans, and Shulman (1994) reported that of 55 survivors of road vehicle accidents (UCS), 21 (38%) developed a phobia of driving (CS). Furthermore, 80% of the subjects with a severe weather phobia indicated that their fear began after experiencing a severe storm (Westefeld, 1996). Likewise, choking phobia is nearly always the result of a traumatic incident in which the patient chokes on, for example, a fishbone (Greenberg, Stern, & Weilburg, 1988).

The classical conditioning model of specific phobias explains why persons react with subjective fear and physiological arousal when they are exposed to the phobic CS. It does not, however, account for the persistent avoidance behavior that phobics display. The influential two-stage theory of Mowrer (1960) attempts to incorporate this point. Briefly, Mowrer's theory assumes that the development of phobias involves two stages. During the first stage, a pairing of a neutral CS and an aversive UCS results in a conditioned fear response to the CS. During the second stage, the person learns that fear responses to the CS can be reduced by avoiding the CS. A reduction in fear levels that follows avoidance is experienced as a positive state. Consequently, avoidance behavior is reinforced and in time becomes an integral part of the phobic fear. Again, research shows that the scenario depicted by the two-stage theory works in the laboratory. Thus, when subjects are confronted with pairings of light (CS) and shock (UCS) and then are given the opportunity to react with an escape response every time the CS appears, persistent avoidance responding occurs (Malloy & Levis, 1988).

The two-stage theory of phobic fear has straightforward treatment implications. According to this theory, avoidance behavior maintains phobic fear because it prevents prolonged exposure to the phobic object. Consequently, phobic subjects have no opportunity to experience that the phobic CS is no longer accompanied by an aversive UCS. The treatment lesson to be learned from this is that one should confront phobic subjects with their phobic CS while ensuring that they do not react with avoidance to this CS. This strategy, known as exposure therapy, has proven to be very successful in the treatment of specific phobias (Marks, 1987; Öst, 1989).

6.20.4.2 Shortcomings of the Traditional Conditioning Approach

In the 1970s, several authors drew attention to the fact that the classical conditioning model of phobias and its extension, Mowrer's two-stage theory, suffered from a number of serious shortcomings (Eysenck, 1979; Rachman, 1977). First, the conditioning approach fails to explain why specific fears are nonrandomly distributed. Indeed, from a conditioning point of view, one would expect that each object can become a phobic stimulus (CS), provided that it is followed by an aversive event (UCS). As previously stated, this is obviously not the case. For instance, fear of snakes occurs more often than fear of electricity, although there is no obvious reason to suspect that snakes are more frequently associated with UCSs than electricity (Agras, Sylvester, & Oliveau, 1969).

Second, in the literature, excellent illustrations can be found of aversive situations (UCSs e.g., air raids) in which, contrary to all predictions that can be derived from the classical conditioning model, people did not acquire phobic fears (e.g., Saigh, 1984). In the aforementioned study of Kuch et al. (1994) not all accident survivors developed a fear of driving. Similarly, there is abundant evidence to show that aversive experiences (UCSs) with spiders, dentists, or dogs do not give rise to spider phobia, dental phobia or dog phobia, respectively (Merckelbach, Arrindell, Arntz, & De Jong, 1992; Lautch, 1971; DiNardo, Guzy, & Bak, 1988). Clearly, then, trauma (UCS) without subsequent phobia occurs.

Third, over the years, it has become clear that not all specific phobias can be traced back to a confrontation with a traumatic or aversive event (UCS). In other words, some people develop a fear response to a CS, although this CS has never been paired with a UCS (Wolpe, Lande, McNally, & Schotte, 1985). In other words, phobia without preceding trauma (UCS) occurs.

These and other shortcomings of the traditional conditioning approach to phobias paved the way for two types of revision. The first type of revision stressed that conditioning concepts should be connected with biological notions in order to understand the etiology of phobias. The aforementioned preparedness hypothesis (Seligman, 1971) is a good example of such a biologically oriented revision. This hypothesis assumes that conditioning interacts with evolutionary processes to produce phobic fear. Thus, aversive events (UCSs) in the context of evolutionary recent objects (e.g., electricity) would not produce a phobic fear, whereas such events in the context of evolutionary relevant items (e.g., snakes) would easily give rise to a phobic fear. Several experiments have tested this idea in the laboratory. By and large, the results of these experiments are disappointing in that they found no evidence for a connection between ease of conditioning and evolutionary relevance of the CS (Hugdahl & Johnsen, 1989).

Another attempt to revise the conditioning model along biological lines proposes that the phobogenic effects of CS–UCS pairings interact with the neurohormonal state of the organism (Kelley, 1987). In Kelley's words: "neuroses = conditioning × neurohormones" (p. 403). More specifically, Kelley argues that high levels of adrenocorticotropic hormone (ACTH) and vasopressin enhances the effects of CS–UCS pairings whereas high levels of endogenous opioids (i.e., endorphins) attenuate these effects. Accordingly, individual differences in neurohormonal levels might explain why, for example, an automobile accident produces a driving phobia in some people, but not in others (Kuch et al., 1994): some subjects are more vulnerable to CS–UCS pairings because they habitually have heightened levels of ACTH and vasopressin and/or lowered endorphin levels. Although it is evident that phobic fear is accompanied by elevated or reduced levels of certain (neuro)-hormones (Cameron & Nesse, 1988), Kelley's proposal has not been put to a direct test. All that one can conclude from the evidence at hand is that lowering the endorphin levels by applying naltrexone (i.e., an opioid antagonist) intensifies fear in subjects who are already phobic (Merluzzi, Taylor, Boltwood, & Götestam, 1991; Arntz, Merckelbach, & De Jong, 1993).

A related line of research has stressed the involvement of sex hormones in the acquisition of phobic fear. For example, in their review Cameron and Nesse (1988, p. 291) conclude that "sex hormone fluctuations in women during the menstrual cycle may be related to changes in anxiety levels, although fluctuations have not always been observed." Interestingly, Van der Molen, Merckelbach, and Van den Hout (1988) found that pre-menstrual women show an increased susceptibility to fear conditioning. Sex hormone fluctuations may also explain why specific phobias are more often found in women than in men.

6.20.4.3 Neoconditioning Model

The second type of revision of the classical conditioning model is more cognitively oriented. Advocates of this approach point out that conditioning is not the blind, reflexive process that it is often assumed to be (Van den Hout & Merckelbach, 1991). The critical question to be asked is: what exactly happens during conditioning? Take the example of little Albert. Did conditioning result in a reflexive connection between the white rat stimulus (CS) and the fear response (CR)? Or did little Albert learn that the white rat stimulus (CS) predicts the onset of the noise stimulus (UCS) and was it this knowledge that elicited a CR? The first scenario is called S-R learning; the second scenario is known as S-S learning. There are good reasons for believing that, in humans, S-S learning is the most common classical conditioning scenario. That is to say, conditioning is usually a cognitive process during which one learns that the CS predicts the UCS (Rescorla, 1988). It is important to note that an S-S approach (i.e., the neoconditioning model) has a number of interesting ramifications and is able to avoid some of the inadequacies of the traditional conditioning model (Rachman, 1991). Two specific aspects of the neoconditioning model deserve comment.

First, the neoconditioning model emphasizes the phenomenon of latent inhibition. Suppose a subject has extensive experience with a CS (e.g., light) that is not followed by an aversive UCS. What will happen when this subject is later exposed to a new situation in which the CS is suddenly accompanied by a painful UCS (e.g., electric shock)? Will the CS now elicit a conditioned fear response? The answer is no. Laboratory experiments show that it is difficult to condition fear responses to a familiar CS that was formerly never associated with an aversive UCS (Booth, Siddle, & Bond, 1989). Recall that, during conditioning, subjects learn that a CS is the predictor of a UCS. If the subject has experienced a number of times that the CS predicts nothing, an incidental co-occurrence of the CS with an aversive UCS is not powerful enough to make the subject believe that the CS has changed into a predictor of the UCS. In other words, prior experiences with the CS inhibit fear conditioning. A study by Doogan and Thomas (1992) nicely illustrates that the mechanism of latent inhibition is relevant when one tries to understand how trauma (UCS) without phobia can occur. These researchers found that traumatic encounters with dogs are reported by both subjects with fear of dogs and subjects without fear of dogs. However, the latter group reported more previous nonaversive contacts with dogs. In other words, the nonfearful subjects had experienced many occasions on which dogs (CS) did not attack. This suggests that in the nonfearful group, latent inhibition helped to minimize the effects of fear conditioning (Davey, 1989a; De Jongh, Muris, Ter Horst, & Duyx, 1995b).

A second phenomenon that must be considered is called UCS inflation (Davey, 1989b). Briefly, this phenomenon refers to a situation in which subjects are exposed to pairings of a CS and a mild UCS. As a result of this, subjects acquire an S–S association. However, given the low intensity of the UCS, this S–S association leads to a weak conditioned fear response (CR). Now, the following may happen: if subjects during a next phase learn that the UCS is nevertheless dangerous, this postconditioning information will lead to an inflation of the UCS value. Consequently, the conditioned fear response will grow in strength. A clinical example taken from White and Davey illustrates how this kind of scenario can account for cases in which conditioned fear emerges without pertinent trauma:

> an individual may witness an unknown person die of a heart attack on a bus or a train. On future occasions, riding on public transport may evoke memories of this incident but no anxiety. ... Subsequently, however, that individual may be present when a close friend or relative dies of a heart attack, thus inflating the aversive properties of heart attacks. This may then give rise to acute anxiety when riding on public transport. In this particular scenario, public transport has never been directly associated with anxiety-eliciting trauma, but the public transport phobia results from a prior learned association between public transport and heart attacks, and subsequent independent inflation of heart attacks as aversive events. (White & Davey, 1989, p. 165)

To recapitulate, neoconditioning concepts such as latent inhibition and UCS inflation can deal with some inadequacies of the traditional conditioning approach. More specifically, latent inhibition can explain why UCS trauma does not always lead to phobia, whereas UCS inflation can explain why phobia without pertinent UCS trauma is possible. Apart from that, these concepts have implications for the treatment of phobias (Davey, 1992). For example, one may use the principle of latent inhibition as a way of producing immunization against the effects of subsequent CS–UCS trials. Giving dental patients a series of painless sham treatments will probably reduce the likelihood that a subsequent painful treatment results in a dental phobia (De Jongh et al., 1995b). As another example, the principle of UCS inflation suggests that, during treatment, it might be worthwhile to systematically devaluate the UCS. In the case of dental phobia, this could mean that one stresses the point that aversive experiences result in healthy teeth.

6.20.4.4 Indirect Pathways to Phobia: Modeling and Information

The classical conditioning pathway to fear assumes that the subject has direct experience with the CS and the UCS. This is true for straightforward conditioning in which a CS is paired with a traumatic UCS, as well as for subtle conditioning scenarios such as latent inhibition and UCS inflation. However, there are cases in which subjects develop a specific phobia although they have no history of direct experience with the CS (i.e., phobic object) and/or UCS (Rachman, 1991). In these cases, indirect pathways of fear acquisition might play a pivotal role. Rachman (1991) provides a detailed description of two indirect pathways that are important in this context: modeling (imitation or vicarious transmission of fear) and negative information.

The modeling pathway assumes that phobic fears can be acquired by watching parents or peers reacting fearfully to a stimulus (e.g., a spider). This assumption is supported by animal and human laboratory studies. For example, Cook and Mineka (1989) found that rhesus monkeys can acquire a fear of snakes through watching videotapes of two model monkeys reacting fearfully to toy snakes. Likewise, Hygge and Öhman (1978) demonstrated that subjects respond with sympathetic activation to pictures of, for example snakes when they have previously watched others reacting fearfully to these pictures. The reverse is also true: the pioneers of behavior therapy already knew that it is possible to eliminate specific fears by presenting nonfearful models and enhancing social learning through modeling (Kornfeld, 1989).

It seems obvious that negative verbal information about certain stimuli such as that provided by books, television, or significant others may give rise to fear of these stimuli. If this was not the case, prevention programs concerned with smoking or AIDS would make no sense. Although there is a paucity of experimental studies on the fear-evoking characteristics of negative information, social psychological studies show that subjects assign more value to negative than to positive information. There might be good evolutionary reasons for this asymmetry (Pratto & John, 1991).

Assuming that modeling and negative information transmission are closely tied to familial interactions, one would expect that there is a familial aggregation of specific phobias. A study by Fyer et al. (1990) shows this to be the case. These researchers found, for example, that 31% of the relatives of specific phobia probands as compared to 11% of control relatives had a life-time diagnosis of specific phobia. Although this study did not distinguish between different etiological mechanisms (genetic inheritance, modeling, etc.), its results are consistent with the idea that modeling and information do operate in families. Likewise, a recent study by Muris, Steerneman, Merckelbach, and Meesters (1996) demonstrated that fears reported by children are a function of the extent to which mothers express their own fears in the presence of their children. This association was independent of the influence of trait anxiety levels in mothers.

6.20.4.5 Disgust Sensitivity

Disgust sensitivity is believed to play a role in the etiology of certain types of specific phobias, especially animal phobias (Matchett & Davey, 1991). For example, several studies have found that spider-phobic subjects have a higher disgust sensitivity than nonphobic subjects (Merckelbach, De Jong, Arntz, & Schouten, 1993). Furthermore, spider-phobic subjects consider spiders to be more disgusting than do nonphobic subjects (De Jong, Andrea, & Muris, 1997). Finally, behavioral treatment results in a parallel decline of fear of spiders and spiders' disgust-evoking status (De Jong et al., 1997). These data indicate that there is a clear association between disgust and disgust sensitivity on the one hand, and clinical manifestations of spider fear on the other hand.

It should be noted that most studies on disgust and phobia are correlational in nature, and that they do not rule out the possibility that fear enhances disgust and/or disgust sensitivity rather than vice versa. However, an experiment of Webb and Davey (1992) indicates that fear can be causally affected by disgust. In that study, it was found that exposure to revulsive material (such as video scenes of a medical operation) leads to an increase in fear of, for example, spiders or snakes.

6.20.4.6 Retrospective Clinical Studies

Several studies have examined to what extent the aforementioned pathways to fear play a role in the etiology of specific phobia (Kleinknecht, 1994; Merckelbach et al., 1992; Öst, 1987). Most of these studies have used the Phobic Origin Questionnaire (POQ; Öst & Hugdahl, 1981), a self-report instrument that asks phobic patients to indicate to what degree their phobia developed along a direct (i.e., conditioning) and/or an indirect (i.e., modeling, negative information) pathway. A potential problem in these studies is that phobics are invited to provide a retrospective judgement as to the cause of their complaints. With this type of research strategy, all kinds of biases (e.g., memory distortions) may occur. On the other hand, Brewin, Andrews, and Gotlib (1993) have summarized evidence to show that claims about the unreliability of retrospective reports are often exaggerated.

Several interesting findings have emerged from the POQ studies. First, although each of the three pathways is represented in the various types of specific phobia, there are large differences between the types. For example, animal phobics and blood–injection–injury phobics more often ascribe their fears to modeling and negative information than claustrophobics. In contrast, the conditioning pathway is more pronounced in claustrophobia than in animal, blood–injection–injury illness or height phobia (Menzies & Clarke, 1993; Öst, 1987). Interestingly, Öst (1987) found evidence to suggest that modeling and negative information are associated with an early onset age. Second, several studies (Merckelbach, Arntz, & De Jong, 1991; Ollendick & King, 1991) have found that fearful subjects often report more than one pathway. There are even indications that subjects with mixed pathways (e.g., conditioning and modeling) have higher levels of fear. Finally, the three pathways to fear are also found in fearful and phobic children aged 9–14 years (Merckelbach, Muris, & Schouten, 1996; Ollendick & King, 1991). This suggests that these etiological mechanisms do, indeed, operate during the early developmental phases.

6.20.5 MAINTENANCE OF PHOBIC FEARS

Specific phobias are acquired on the basis of direct or indirect learning pathways. But how are phobic fears maintained, once they are acquired? As mentioned earlier, Mowrer's (1960) two-stage model suggests that avoidance behavior is responsible for the conservation of phobic fear: avoidance would minimize direct and prolonged contact with the phobic object and, hence, phobics would not have the opportunity to learn that the CS is a neutral object or otherwise extinguish fear response.

Although the role of avoidance behavior in the conservation of fear seems self-evident, there are other mechanisms that are highly relevant in this context. These mechanisms are cognitive in nature and have been the object of extensive research in the past years (Dalgleish & Watts, 1990; Mineka & Sutton, 1992). There is agreement among most researchers in this field that pathological anxiety (e.g., specific phobia) is not accompanied by a general cognitive dysfunction. In other words, it is not the case that pathological anxiety is associated with deficits in memory, attention, motor function and so on. Instead, cognitive dysfunctions in specific phobias are restricted. First, phobic subjects show evidence of dysfunctions in attentional and inferential (i.e., judgmental) processes. In contrast, depressive patients exhibit dysfunctions in memory rather than attention or judgment (Mineka & Sutton, 1992). Second, the attentional and judgmental biases that characterize phobias are domain specific. That is to say, these biases become apparent if and only if subjects are confronted with fear-relevant stimuli (e.g., the word spider in case of a spider phobic subject).

6.20.5.1 Attentional Bias

Attentional bias refers to the phenomenon of hyperattention to threatening material. One frequently employed technique for demonstrating attentional bias is the modified Stroop color task. This task requires subjects to name the color of a word while ignoring the meaning of that word. A consistent finding in Stroop studies with anxious patients is that their color naming of threatening words is slower than that of neutral words (Eysenck, 1992). For example, spider phobics display retarded color-naming times when they are confronted with spider-related words (e.g., web), but not when they have to color name neutral words (e.g., car). This is because spider phobics automatically direct their attention to the content of the threatening words and this interferes with their main task (i.e., color naming). Note that the phenomenon of attentional bias accords well with Öhman's (1993) hypothesis of a "quick and dirty" subcortical transmission route of phobic information (discussed above). Interestingly, the attentional bias may disappear in successfully treated spider phobics (Watts, McKenna, Sharrock, & Trezise, 1986). As to the clinical consequence of attentional bias, it seems likely that an increased focus on danger and threat stimuli perpetuates phobic fear: attentional bias implicates an increased encoding of threatening material and this, in turn, will elevate fear levels (Mineka & Sutton, 1992).

6.20.5.2 Judgmental Bias

Two types of judgmental bias probably play a role in the maintenance of specific phobia. The first is covariation bias, the tendency to overestimate the association between phobic stimuli and aversive outcomes (Tomarken, Mineka, & Cook, 1989). The experimental demonstration of covariation bias in phobias is straightforward. Phobic and normal subjects are shown a series of slides consisting of fear-relevant (e.g., spiders) and fear-irrelevant pictures (e.g., flowers). Slide offset is followed by one of three outcomes: an aversive shock, a tone, or nothing. Fear-relevant and fear-irrelevant pictures are equally often followed by each of the outcomes. After the series of slides, subjects are asked to estimate the contingencies between slides and outcomes—if a spider picture appeared, how great was the chance that this picture was followed by a shock? Under these experimental conditions, phobic subjects systematically overestimate the contingency between phobic stimuli and aversive outcomes. Again, in successfully treated spider phobics, the covariation bias disappears (De Jong, Merckelbach, Arntz, & Nijman, 1992). De Jong, Van den Hout, and Merckelbach (1995) found a strong and positive correlation between residual covariation bias in treated spider phobics and relapse: the stronger the (post-treatment) overestimation of the contingency between spider picture and aversive shock, the higher the spider fear at two-year follow up. The implication of this covariation bias is clear: phobics have a tendency to attribute aversive experiences to the phobic object and this, in turn, will sustain phobic fear.

A second judgmental bias that may occur in specific phobias is a style of reasoning known as *ex consequentia* inference. Like other people, phobics believe that dangerous situations elicit anxiety. However, unlike many nonphobic subjects, spider phobics seem to believe that anxiety symptoms imply the presence of danger, such as dangerous spiders (Arntz, Rauner, & Van den Hout, 1995). The *ex consequentia* inference probably serves to legitimize the phobic fear and, thus, may maintain the phobia. However, more studies are needed to firmly establish the role of this reasoning style in the maintenance of fear.

6.20.5.3 Thought Suppression

As mentioned earlier, phobic patients are frequently disturbed by anxiety-arousing thoughts. To avoid feelings of discomfort, phobic patients may try to suppress such thoughts. However, research has shown that thought suppression has paradoxical effects. That is, the effort "not to think about" a particular thought may, in fact, lead to the continuation of that thought (Wegner, Schneider, Carter, & White, 1987).

Several authors (Salkovskis, 1989; Wegner, 1989) have put forward that thought suppression might play a role in the etiology and maintenance of anxiety disorders such as specific phobias. In a recent study, Muris, De Jongh, Merckelbach, Postema, and Vet (in press) found some evidence for this claim. In their study, effects of thought suppression in phobic and nonphobic dental patients were examined. The results were as follows. First, as expected, phobic patients reported higher levels of intrusive and negative thinking during dental treatment than nonphobic patients. Second, phobic patients tried harder to suppress their negative thoughts than nonphobic subjects. Finally, in the nonphobic group, suppression resulted in increased levels of anxiety and intrusive thinking. Altogether, the findings suggest that thought suppression is related to pathological manifestations of dental fear. That is to say, suppression intensifies fear in nonphobic subjects, whereas it appears to be part of the habitual "coping" style in phobic patients.

6.20.6 TREATMENT OF SPECIFIC PHOBIAS

6.20.6.1 Exposure-based Treatments

Exposure *in vivo* is the treatment of choice for specific phobias (Marks, 1987; Rachman, 1990). Exposure treatment involves graded and prolonged confrontation with the phobic object. Meanwhile, the therapist encourages the patient to approach the phobic object and to refrain from avoidance behavior. Exposure is often combined with other techniques: modeling by the therapist in the case of animal phobias (Öst, 1989), applied tension to prevent fainting in the case of blood–injection–injury phobias (Öst, Fellenius, & Sterner, 1991a), and cognitive interventions to correct catastrophic misinterpretations of bodily symptoms in the case of claustrophobia (Craske et al., 1995). Exposure treatments yield good results: success percentages of 90% are no exception. Furthermore, controlled studies show that the efficacy of exposure is maintained at long term follow-up (Öst, 1996; Öst et al., 1991b).

The precise mechanism underlying the beneficial effects of exposure are a matter of considerable debate. Some authors have favored an extinction or habituation interpretation of exposure effects (Marks, 1987; Watts, 1979). According to these authors, exposure is the extinction or habituation of a fear CR to a CS that is no longer followed by a UCS. Other authors have argued that exposure effects are linked to cognitive changes rather than response habituation (Foa & Kozak, 1986). They emphasize that, during exposure, the patient learns that the phobic object is not associated with catastrophic events. This will eventually lead to a correction of the phobic fear. This formulation is compatible with the S-S view of phobic fear (Eysenck, 1987), and also with cognitive theories about phobic fear (Last, 1987). There is preliminary evidence that the interpretations of exposure that emphasize cognitive change are closer to the truth than extinction/habituation accounts. For example, Shafran, Booth, and Rachman (1993) recently showed that treatment of claustrophobia is successful to the degree that it corrects certain key cognitions (e.g., "I will suffocate"). Similarly, in their study of one-session exposure treatment of spider phobia, Öst et al. (1991b, p. 421) remark that "the clinical impression from treating these patients is that the most important factor in the one-session treatment is making explicit the patients" catastrophic thoughts concerning the phobic situation and devising the exposure situation in such a way that these can be tested out."

6.20.6.2 Eye Movement Desensitization and Reprocessing

Eye movement desensitization and reprocessing (EMDR) is a relatively new technique that was originally proposed as a treatment method for post-traumatic stress disorder (Shapiro, 1989). During EMDR, patients imaginally expose themselves to a traumatic or aversive memory, while simultaneously engaging in lateral eye movements that are induced by the therapist. The idea is that through eye movements, negative memories are emotionally processed and assimilated. The therapist-induced eye movements would simulate the inhibitory function of rapid eye movement (REM) sleep. Some authors have claimed that EMDR is not only effective in post traumatic stress disorder, but also in specific phobias (Marquis, 1991; Shapiro, 1995). However, this claim rests entirely on case studies. Controlled outcome studies designed to compare the effectivity of EMDR and exposure *in vivo* in the treatment of specific phobias indicate that exposure yields better results, especially on the behavioural level of fear (Muris & Merckelbach, 1997; Muris, Merckelbach, van Haaften, & Mayer, 1997).

6.20.6.3 Benzodiazepines

There is abundant evidence showing that benzodiazepines have anxiolitic effects (Rickels, 1978). Furthermore, animal research indicates that benzodiazepines inhibit conditioned fear responses. Consequently, one would predict that benzodiazepines can be useful in the treatment of specific phobias. However, studies designed to evaluate the effect of benzodiazepines on phobic avoidance have generally yielded disappointing results (Bernadt, Silverstone, & Singleton, 1980; Sartory, MacDonald, & Gray, 1990). Although benzodiazepines might inhibit subjective fear during phobic confrontation, they do not increase approach behavior (Sartory et al., 1990). Gray (1987) has gone one step further and suggested that benzodiazepines might even be harmful in that they create state dependency effects: phobics learn to approach the phobic stimulus when drugged, but this learning is not transferred to a nondrugged state.

6.20.7 CONCLUSIONS

Specific phobias have been well researched. As a result, we now have a comprehensive picture of the important elements that constitute this disorder. To summarize the most important points, specific phobias form a heterogeneous class of disorders (Himle, Crystal, Curtis, & Fluent, 1991). The most radical difference is found between animal phobias and claustrophobia. Compared to animal phobias, claustrophobia is characterized by a more elaborated set of cognitions, a later age of onset, and a more pronounced role of conditioning experiences in the etiology (Öst, 1987). Accordingly, in claustrophobia, but not in animal phobias, effects of exposure treatment are enhanced when the treatment is combined with cognitive interventions (Craske et al., 1995).

Specific fears are common in childhood and there are reasons to believe that cognitive development is closely linked to the content of these fears. In most children these fears represent transitory phenomena. In a small subgroup of children and adolescents, the specific fears become chronic due to conditioning, modeling, negative information and/or a heightened disgust sensitivity. It is also possible that neuroticism may make a general genetic contribution to the acquisition of such phobias. Once a specific phobia exists, it is maintained by processes such as cognitive biases and thought suppression. Consequently, in most cases, the natural course of specific phobias is chronic. However, exposure-based treatments are very effective in reducing specific phobias.

In summary, research has yielded a clear picture of the etiology and maintenance of specific phobias, and of how this disorder should best be treated. Hopefully, in the future, clinicians will profit more from this information than they often do now (Andrews, Hadzi-Pavlovic, Christensen, & Mattick, 1987).

6.21.1 INTRODUCTION

Social anxiety is a common experience, and most individuals can recall some event in their lives when they experienced concern about being evaluated by others. Anyone who has interviewed for a job, given a presentation, or gone on a first date with someone to whom they were attracted has experienced the concerns associated with coming under the scrutiny of others. When anxiety in these situations becomes severe and interferes with the adaptive functioning of the individual, the diagnosis of social phobia may be assigned. The following are examples:

> Mr S., a man in his mid-20s, reports being anxious when meeting new people. Nevertheless, he managed to graduate from high school and secure a job in sales which appears to cause him little difficulty. He has a small circle of friends from his adolescent years but is very uncomfortable when meeting anyone for the first time. He actively avoids socializing in situations which may involve "too many new people." He managed to meet and marry a woman two years ago, but she is frustrated by his reluctance to meet new people. Mr. S. copes, in part, by smoking marijuana with his small circle of friends. He has also recently begun to use marijuana on his own outside of social situations. He is not happy about this behavior but reports that it is the only thing that calms him down after a long day of interacting with others.
>
> Ms. B. is a single woman in her late 30s who currently works as a reference librarian. She has dated only occasionally, and her social life is a source of much distress. She dreams of having a family but doubts her ability to achieve this dream. She has become more depressed, beginning to feel hopeless about her future prospects. To complicate her situation, the library is beginning a new outreach program and she will be expected to speak with students in the local schools, something she dreads. She seeks treatment now for what she views as her last opportunity to turn her life around.

As these examples illustrate, social phobia can be a debilitating disorder, causing considerable impairment in occupational, educational, and social functioning. Individuals with social phobia often have difficulty making friends, finding partners, and remaining socially connected to others. They may make important career decisions which accommodate their social anxiety even if these decisions make it unlikely that they will achieve their personal goals. For example, they may opt for college courses which require no public speaking, choose vocations because they present few demands for social interaction, or simply opt out of employment altogether. Some may settle for an easily available romantic partner regardless of level of attraction. Understanding social phobia and its concomitants is a crucial task, especially since social phobia may be much more common than previously believed. The recognition of social phobia and knowledge of effective treatment options are important considerations for the clinical psychologist.

6.21.1.1 Definition of Social Phobia

Our understanding of social phobia has evolved considerably since the 1960s, and it is instructive to examine that evolution in some detail. One of the first descriptions of social phobia was provided by Marks and Gelder (1966). Social phobia was described as the experience of anxiety in situations where an individual might perform some task under the scrutiny of others. These "performance" tasks included public speaking, writing or eating in front of others, and using public restrooms while others were present. Fears expressed by the individual with social phobia in these situations focused primarily on one of two concerns: that the individual would do or say something embarrassing or that symptoms of anxiety would be visible to others. When these performance tasks could adequately be performed in the absence of others, social phobia was said to be present.

This early conceptualization provided the framework for the diagnostic criteria for social phobia in the third edition of the *Diagnostic and statistical manual of mental disorders* (*DSM-III*; American Psychiatric Association [APA], 1980). Social phobia was defined by the experience of fear in and a compelling desire to avoid one of several specific situations. Notably absent from this early view was anxiety associated with interpersonal interaction. Interpersonal anxiety was not considered to be part of the social phobia "picture," and individuals with this type of anxiety were instead given the Axis II diagnosis of avoidant personality disorder (APD). This, however, would change with the next revision of the diagnostic criteria.

As more was learned about individuals with social phobia, it became apparent that many individuals who experienced anxiety in performance situations also feared interacting with others. Thus, when the revision of *DSM-III* (*DSM-III-R*; APA, 1987) was published, the scope of the diagnosis was broadened to include social interactional fears. Several additional findings and concerns supported this decision, including research documenting that most patients with social phobia reported multiple fears (Turner, Beidel, Dancu, & Keys, 1986), the observation that clinicians often applied the diagnosis of social phobia to individuals with multiple social fears (Spitzer & Williams, 1985), and the concern that classifying interpersonal anxiety as an Axis II disorder might discourage research into its treatment (Liebowitz, Gorman, Fyer, & Klein, 1985) (see Heimberg, 1996, for a more detailed discussion of these issues).

With the broadening of the diagnostic criteria, a generalized subtype was added to describe those individuals with social phobia who feared most social interactions. Avoidance, while common, was not essential for the diagnosis in recognition of the fact that some individuals with social phobia often endure the personal distress associated with feared situations. Social phobia, previously viewed as rare and rarely debilitating, was described as much more common and associated with potentially severe impairment.

The definition of social phobia remains essentially unchanged in the *DSM-IV* (APA, 1994). Our knowledge of social phobia has matured as further research has been conducted and our knowledge base has expanded. In fact, two important volumes have been published surveying the current "state of our knowledge" regarding this disorder (Heimberg, Liebowitz, Hope, & Schneier, 1995; Stein, 1995). What was once described as a "neglected anxiety disorder" (Liebowitz et al., 1985) is now much better understood.

6.21.1.2 Description of Social Phobia

6.21.1.2.1 Prevalence

In the National Institute of Mental Health Epidemiological Catchment Area (ECA) studies, the six-month prevalence for *DSM-III* social phobia was reported to be 1.5–2.6% for women and 0.9–1.7% for men (Myers et al., 1984). The lifetime prevalence of social phobia at four ECA sites was 2.4% for men and women combined (Schneier, Johnson, Hornig, Liebowitz, & Weissman, 1992). More recently, the National Comorbidity Survey (NCS; Kessler et al., 1994) was conducted in the United States with a national probability sample of more than 8000 participants between the ages of 15 and 54 years. The 12-month prevalence of *DSM-III-R* social phobia was reported to be 7.9% (6.6% for men and 9.1% for women), and the lifetime prevalence of social phobia was reported to be 13.3% (11.1% for men and 15.5% for women). The high lifetime prevalence of social phobia makes it the third most common mental disorder examined in the NCS after major depression (17.1%) and alcohol dependence (14.1%).

Similar prevalence rates for *DSM-III-R* social phobia were reported in two other studies conducted outside the United States. A study of 470 Swiss adults revealed a lifetime prevalence rate of 16% for *DSM-III-R* social phobia, similar to the rate reported in the NCS (Wacker, Mullejans, Klein, & Battegay, 1992). In Winnepeg, Manitoba, a telephone survey examined the nature of social anxiety in the community as well as the prevalence of *DSM-III-R* social phobia (Stein, Walker, & Forde, 1994). Of 526 respondents, 7.1% met criteria for the diagnosis of social phobia at the time of assessment, similar to the 12-month NCS prevalence rate.

The higher prevalence rates reported in these studies compared with the much lower rates reported in the ECA studies may arise from multiple sources. For example, there were a number of methodological differences between the ECA and NCS studies that might account for differences in reported prevalence. Specifically, in the ECA studies, interviewers inquired about the individual's anxiety in only three situations (eating in front of others, public speaking, and speaking to strangers or meeting new people). The NCS interview inquired about fear in these three situations, but also queried three additional situations: using toilets away from home, writing while being watched, and sounding foolish in front of others. Since both studies required endorsement of fear and interference in only one situation in order to receive a diagnosis of social phobia, the odds of a positive diagnosis were higher in the NCS than the ECA. Furthermore, the probe regarding "sounding foolish in front of others" reflects the broadening of the social phobia diagnosis to include a greater focus on anxiety in social interaction, not reflected in *DSM-III.* Clearly, the increase in the number of situational probes, as well as the broadening of the scope of inquiry to include more social interaction situations, may identify more individuals with social phobia.

Methodological differences and criterion changes may not be the only reasons that prevalence rates differ between studies. Magee, Eaton, Wittchen, McGonagle, and Kessler (1996) report that the prevalence of social phobia may, in fact, be increasing. Analysis of the NCS data demonstrated the existence of cohort effects, such that younger cohorts of subjects (ages 15–24) showed higher prevalence rates than older cohorts (ages 25 and up). These findings were most pronounced for agoraphobia, but were also noted for simple and social phobia. This trend towards increasing prevalence rates in younger cohorts has also been noted for major depression in several studies around the world (Cross-National Collaborative Group, 1992; Klerman & Weissman, 1989; Wickramaratne, Weissman, Leaf, & Holford, 1989).

6.21.1.2.2 Gender ratio

Epidemiological data suggest that more women than men suffer from social phobia. For example, across four ECA sites, approximately 70% of individuals with social phobia were women (Schneier et al., 1992). In the NCS, women with social phobia outnumbered men with social phobia about 1.4 to 1. This gender difference in prevalence is not apparent in treatment settings, however, where men and women with social phobia present in approximately equal numbers (Mannuzza, Fyer, Liebowitz, & Klein, 1990). This may be related to different sociocultural expectations for men and women. For example, women perceived as shy may fit stereotypical images of femininity and experience less demand to overcome their social anxiety. Conversely, men may experience more pressure to alter their social anxiety and avoidance which are less consistent with stereotypical conceptions of masculinity.

The study of gender differences was extended to examine whether there were differences between men and women with social phobia in the severity of their anxiety or in the nature of the situations in which they reported clinically significant anxiety (Turk, Heimberg et al., in press). Women exhibited more severe social fears on several measures. They also reported significantly greater fear than men while talking to authority, acting/performing/giving a talk in front of an audience, working while being observed, entering a room when others are already seated, being the center of attention, speaking up at a meeting, expressing disagreement or disapproval to people they don't know very well, giving a report to a group, and giving a party. Men reported significantly more fear than women regarding urinating in public bathrooms and returning goods to a store. Not surprisingly, more men than women with social phobia reported full-time employment.

6.21.1.2.3 Age of onset

Hazen and Stein (1995) reviewed 15 epidemiological and clinical studies and found the mean age of onset of social phobia to range between 13 and 20 years. However, age of onset may differ by subtype of social phobia. For example, Holt, Heimberg, and Hope (1992) found that the age of onset for a sample of subjects with generalized social phobia was about 13 years of age, whereas the age of onset for subjects with nongeneralized social phobia was 22.6 years. This finding was later replicated by Brown, Heimberg, and Juster (1995). To further complicate this picture, data from the NIMH ECA studies reported by Schneier et al. (1992) suggest that the distribution of age of onset of social phobia may be bimodal with one peak at 13 years of age and an earlier peak at under five years of age. This pattern suggests that there may be more than one pathway to the development of social phobia.

6.21.1.2.4 Chronicity

Although no true "natural history" studies of social phobia have been conducted, several lines of research converge to support the perspective that social phobia is a chronic disorder. In one such study, Reich, Goldenberg, Vasile, Goisman, and Keller (1994) followed 140 subjects with social phobia for over one year. Seventy-four subjects were diagnosed with generalized social phobia and the remainder (66) with discrete social phobia (fear of one or more specific performance situations). After 65 weeks, only 11% of the sample achieved full remission despite the fact that 88% received some form of psychotherapy or pharmacotherapy during this period. Importantly, there were no differences in chronicity between subjects with generalized vs. discrete social phobia, suggesting a similar course for these two variants of the disorder.

Studies on shyness, a construct closely related to social phobia, may shed additional light on the issue of chronicity. Shyness, which is not a diagnostic entity, has never been defined consistently by researchers. However, every definition of shyness has included the concept of anxiety regarding social interaction, suggesting that shyness and social phobia are closely allied (Turner, Beidel, & Townsley, 1990). Research reviewed by Turner et al. (1990) examining social phobia and shyness further suggests that the two conditions, while not identical, broadly overlap on behavioral, cognitive, and physiological indices. Rapee (1995) has suggested that the two conditions differ more quantitatively than qualitatively, especially on indices of impairment and avoidance, with social phobia being the more extreme condition. Thus, research on shyness in children and its influence on later levels of functioning may reveal something about the chronicity of social anxiety. One prospective study found that boys identified as shy were likely to marry and achieve occupational stability later in life than nonshy boys (Caspi, Elder, & Bem, 1988). Childhood shyness also influenced girl's later development. Compared with nonshy girls, shy girls were more likely to become housewives or to remain at home after childbirth. Thus, early experiences with social anxiety, specifically shyness in children, were predictive of adult behavior which could be broadly construed as the demonstration of social impairment or avoidance.

Finally, "behavioral inhibition," or the tendency to withdraw in the face of novel people, places, and things, has been identified in very young children and may persist for years (Kagan, Reznick, & Snidman, 1988). Kagan et al. (1988) report that behavioral inhibition occurs in approximately 10–15% of children. A majority of children classified as behaviorally inhibited prior to age three remained inhibited for at least 10 years (Rosenbaum, Biederman, Pollock, & Hirshfeld, 1994). Furthermore, behaviorally inhibited children were more introverted and more physiologically reactive to stress than uninhibited children. More revealing, however, is that the presence of behavioral inhibition in children was associated with a greater occurrence of childhood anxiety disorders (Biederman et al., 1990) and a higher likelihood of anxiety disorders, especially social phobia, in the parents of these children (Rosenbaum et al., 1991).

6.21.1.3 Functional Impairment

Social phobia is often associated with significant impairment in occupational and educational attainment as well as social functioning (Amies, Gelder, & Shaw, 1983; Liebowitz et al., 1985; Magee et al., 1996; Schneier et al., 1992, 1994; Turner et al., 1986). For example, Schneier et al. (1992) re-evaluated the data of subjects with social phobia from four of the five ECA study sites. Subjects with social phobia were less educated, of lower socioeconomic status, and less likely to be married when compared to subjects with other disorders (but not social phobia) and to nondisordered subjects. Another study found that subjects with social phobia were less likely to be married than subjects with agoraphobia, although they also were likely to be younger at the time of referral than the agoraphobic subjects (Amies et al., 1983). Both of these studies examined social phobics diagnosed according to *DSM-III*. However, similar impairment is observed whether *DSM-III* or *DSM-III-R* criteria for social phobia are employed. Magee et al. (1996) reported that *DSM-III-R* social phobia was associated with less educational attainment, lower income, reduced likelihood of being married or employed, and a greater likelihood of living with one's parents. Schneier et al. (1994) compared the self-rated impairment of 32 *DSM-III-R* social phobic subjects who were not currently depressed and a group of normal control subjects. The social phobic subjects reported significantly higher levels of impairment in every category of social functioning (family relations, romantic relationships, and social network) and occupational functioning (education and employment), as well as alcohol and drug use, mood regulation, and activities of daily living. Finally, individuals with social phobia report less satisfaction with their lives than persons without social phobia (Safren, Heimberg, Brown, & Holle, 1997).

6.21.1.4 Comorbidity

Comorbidity is high among individuals with social phobia. Schneier et al. (1992) reported that among ECA subjects with *DSM-III* social phobia, 69% had at least one comorbid disorder (excluding dysthymia and simple phobia). When comparing rates of comorbidity between subjects with social phobia and subjects with other disorders but not social phobia and subjects with no disorders (the latter two groups being combined into a no social phobia group), elevated rates of comorbidity in the social phobia group were found for all disorders studied. For example, simple phobia and agoraphobia were the most commonly occurring comorbid diagnoses in the social phobia group with lifetime rates of 59% and 45%, respectively, compared to rates of 13.2% and 6.1% in the no social phobia group. Other disorders with elevated comorbidity rates were panic disorder (4.7% vs. 1.3%), major depression (16.6% vs. 4.0%), obsessive-compulsive disorder (11.1% vs. 2.5%), somatization disorder (1.9% vs. 0.2%), dysthymia (12.5% vs. 3.1%), and bipolar disorder (4.7% vs. 1.1). When a comorbid disorder was diagnosed, social phobia was the temporally primary disorder 77% of the time.

In the NCS study, 81% of persons with *DSM-III-R* social phobia had at least one other disorder (Magee et al., 1996). Again, social phobia was highly comorbid with simple phobia (37.6%), agoraphobia (23.3%), and major depression (37.2%). Substantial rates of comorbidity were evident for any affective disorder (41.4%) and any anxiety disorder (56.9%). Again, social phobia was the temporally primary disorder in the majority of cases.

Substance-related disorders also commonly co-occur with social phobia. In the ECA studies, 18.8% of social phobics were comorbid for alcohol abuse and 13% for drug abuse (Schneier et al., 1992). In a subset of subjects from the ECA studies, social phobia was highly comorbid with alcohol-related disorders (Himle & Hill, 1991). Nearly 28% of social phobics also had an alcohol-related disorder compared with 13–24% for nonsocial phobics. In the NCS, these figures are even higher. Alcohol abuse and alcohol dependence were diagnosed in over 30% of *DSM-III-R* social phobics, whereas drug abuse and drug dependence were diagnosed in over 20% of social phobics (Magee et al., 1996). Nearly 40% of *DSM-III-R* social phobics had a comorbid substance-related disorder.

While alcohol-use disorders are more common in social phobics than in the community at large, social phobia is also more common among alcoholics than in the community. Estimates of the prevalence of social phobia in subjects diagnosed with alcohol-related disorders run as high as 40% (Ross, Glaser, & Germanson, 1988; Smail, Stockwell, Canter, & Hodgson, 1984). Kushner, Sher, and Beitman (1990) reported that social phobia was nine times more common among patients with alcohol disorders than in a community sample.

Data provided by Magee et al. (1996) and Schneier et al. (1992) are remarkably consistent despite the differences between the ECA and NCS studies. Comorbidity of social phobia with other anxiety disorders, affective disorders, and substance-related disorders is common. In the majority of cases, social phobia is the temporally primary condition, its onset preceding the onset of comorbid conditions.

6.21.1.5 Social Phobia and Avoidant Personality Disorder

Early on, APD and social phobia were defined as relatively distinct diagnostic entities. Social phobia referred to fear in circumscribed performance situations, whereas APD referred to more broad-based fear of social interaction. With the publication of *DSM-III-R*, changes in the diagnostic criteria were introduced which blurred the distinction between these two disorders. For example, the generalized subtype of social phobia, added in *DSM-III-R*, referred to fear in most social situations, a profile which previously would have excluded a diagnosis of social phobia. Also, the criteria for APD were modified such that there was now a greater emphasis on fear of negative evaluation and social discomfort, a central feature of social phobia. Whereas in *DSM-III*, five of five criteria had to be met for the diagnosis of APD, only four of seven were required in *DSM-III-R*, making it easier for the diagnosis to be awarded. This situation remains essentially unchanged in *DSM-IV* (see Heimberg, 1996, for a fuller discussion of the issues related to generalized social phobia and APD).

A number of articles have addressed the degree of overlap between generalized social phobia with and without APD (Brown et al., 1995; Herbert, Hope, & Bellack, 1992; Holt et al., 1992; Schneier, Spitzer, Gibbon, Fyer, & Liebowitz, 1991; Tran & Chambless, 1995; Turner, Beidel, & Townsley, 1992). Despite differences in sampling procedures, subtype definition, and diagnostic instruments, the degree of overlap was high, ranging from 25 to 89% in these six studies. Widiger (1992) concluded that generalized social phobia and APD were more alike than not and that the combination of generalized social phobia and APD probably represents a more severe manifestation of social phobia.

Differential response to treatment by generalized social phobics with and without APD might highlight distinctions between these two disorders, and the effects of treatment designed specifically for social phobia on the diagnosis of APD might further clarify this relationship. Brown et al. (1995) examined these issues in the context of cognitive-behavioral group treatment for social phobia. On the majority of outcome measures, there were no post-treatment differences between generalized social phobics with or without APD. On the remaining measures, social phobics with APD remained more severely impaired. Importantly, 47% (8 of 17) of the patients diagnosed with APD prior to treatment no longer met APD criteria following treatment. Hope, Herbert, and White (1995b) reported that APD did not differentially predict outcome of cognitive-behavioral group treatment for social phobia. However, in this study, subtype of social phobia and APD diagnosis were not considered simultaneously. Feske, Perry, Chambless, Renneberg, and Goldstein (1996) treated generalized social phobics with and without APD with a combination of behavioral techniques (exposure, relaxation, social skills training, and systematic desensitization). Although both groups significantly improved, generalized social phobics with APD began and ended treatment more impaired than social phobics without APD. This pattern of results was also evident at three-month follow-up.

These results lend further support to Widiger's (1992) conclusion noted above, that generalized social phobia and APD differ more quantitatively than qualitatively. In his review, Heimberg (1996) takes this argument a step further by questioning the appropriateness of separating these two diagnoses on to Axis I and Axis II. Most importantly for the clinical psychologist who may be treating generalized social phobics with and without APD is that response to treatment for these subjects appears to be similar.

6.21.1.6 Summary

Social phobia, a chronic anxiety disorder, is highly prevalent in both men and women, and is associated with significant functional impairment and personal distress. Although the average age of onset is in the early teens, some individuals appear to suffer with the disorder from a much earlier age. Comorbidity with other conditions is the rule although social phobia usually begins first. We turn our attention now to possible explanations of the development of social phobia.

6.21.2 UNDERSTANDING THE ETIOLOGY AND MAINTENANCE OF SOCIAL PHOBIA

As knowledge of social phobia has increased, researchers have developed models of the causes and maintaining factors of social anxiety and social phobia (e.g., Clark & Wells, 1995; Heimberg, Juster, Hope, & Mattia, 1995; Leary & Kowalski, 1995; Rapee & Heimberg, 1997). An integrative model of the etiology of social phobia was put forth by Heimberg et al. (1995). Drawing from a broad range of empirical and theoretical literature, they argue for a diathesis-stress conceptualization in which the principal etiological mechanism is an interaction between biological predisposition (Fyer, Mannuzza, Chapman, Liebowitz, & Klein, 1993) and environmental factors. Results from twin studies and family studies combine to support the view that a tendency to interpret situations as potentially threatening may be partially inherited. This general tendency to become anxious and interpret situations as potentially threatening may represent a general response pattern that becomes more specifically focused on social stimuli as a result of environmental factors (Bruch & Heimberg, 1994; Bruch, Heimberg, Berger, & Collins, 1989). Such environmental factors may include a parent's anxiety about social interaction which is communicated to the child directly or indirectly. Parents may also emphasize the opinions of others as excessively important, withhold approval for anything less than perfect performance, and/or isolate their child from social interaction. Early negative peer group interactions may further sensitize individuals to the "potential danger" of social interaction.

Repeated exposure to early sensitizing experiences may contribute to the development of cognitive structures (i.e., schemata) which define other people as inherently critical and social situations as inherently dangerous and threatening to one's self-esteem. Furthermore, the individual may come to believe that only perfect performance would allow him/her to avoid the danger of criticism and negative evaluation by others but that performance up to that standard is highly unlikely (Juster, Heimberg, Frost, et al., 1996). These cognitive structures are postulated to be an underlying, maintaining mechanism for the experience of anxiety in social situations.

Rapee and Heimberg (1997) have delineated a theoretical model of the experience of anxiety when a person with social phobia anticipates or enters a social situation. As noted above, individuals with social phobia make assumptions about the nature of social situations which provide the foundation upon which the experience of social anxiety is built. These assumptions compel them to monitor their performance and others' evaluation of them at all times. Thus, when individuals with social phobia enter social situations, they form mental representations of themselves as they believe they appear to their audience. Simultaneously, they compare their own perception of their performance in this situation with the standard of performance they believe to be held for them by their audience. While attention is given to this internal representation, individuals also attend to the environment, searching for potential threat as well as internal cues (e.g., tachycardia) which may suggest inadequate performance. Negative signs from without or within may then serve as indicators that negative evaluation is likely, and anxiety ensues. The entire experience has further negative impact as it may serve to strengthen maladaptive beliefs and lower expectations for success in similar future situations.

6.21.3 TREATMENT STRATEGIES FOR SOCIAL PHOBIA

Several comprehensive reviews of treatment strategies for social phobia have been written (Heimberg, 1989; Heimberg & Barlow, 1988; Heimberg & Juster, 1995; Hope, Holt, & Heimberg, 1993; Juster, Heimberg, & Holt, 1996) including one which focused on long-term outcome (Juster & Heimberg, 1995). The paper by Heimberg (1989) reviewed just 17 studies. In contrast, the current chapter reviews 37 studies, five of which focus specifically on long-term outcome. The field of social phobia treatment is rapidly growing in size and sophistication.

6.21.3.1 Social Skills Training

Early attempts to treat individuals with social phobia were based on the premise that the person's social anxiety was a result of a deficit in social skills, that is, a lack of knowledge of how to perform or capacity to perform in social situations. Although a logical possibility, there is little empirical support for this notion (Juster & Heimberg, 1995). It is clear that individuals with social phobia exhibit deficits in their social performance; however, this performance deficit has never been linked to a singular cause (i.e., social skills deficit). Possible causes of performance deficits include inhibition of behavior by anxiety or maladaptive beliefs, avoidance of certain situations due to anticipatory anxiety, or a social skills deficit, among others. Our clinical experience suggests that the first two are more likely explanations for the performance deficits seen in social phobic individuals. In clinical settings, social phobics repeatedly perform feared activities as part of exposure exercises during treatment or as part of behavioral assessment tasks, and their performance during these tasks is typically "within normal limits." Despite usually adequate performance, the individual's self-report is almost always marked by negative self-bias (Rapee & Lim, 1992). Although social phobics may report that they do not know what to say or how to act in social situations, their actual behavior often suggests otherwise.

Despite the lack of support for social skills deficits as an overall explanatory mechanism for social phobia, it clearly remains a possibility for some individuals. Whether or not an individual lacks social skills, social skills training (SST) may provide some benefit by providing exposure to anxiety-evoking stimuli, providing information about one's ability to perform in social situations, etc. Social skills training is an amalgam of behavioral techniques designed to give patients experience with and exposure to various types of behavioral practice. Techniques such as therapist modeling, behavioral rehearsal, corrective feedback, social reinforcement, and homework assignments may all be components of social skills training interventions.

6.21.3.1.1 Review of empirical studies of SST

We now turn to the review of treatment strategies designed specifically for the remediation of social skills deficits. Marzillier, Lambert, and Kellet (1976) compared SST with systematic desensitization (SD; the combination of progressive muscle relaxation and the presentation of scenes of gradually increasing anxiety-evoking potential to imagination) in the treatment of 20 subjects who, by description, met criteria for generalized social phobia. This study predated the inclusion of social phobia in the official diagnostic nomenclature, but it appears that subjects would have met criteria for the current conceptualization of the disorder. Subjects were assigned randomly to one of the two treatment conditions (or a wait-list control) and received 15 weekly, 45-minute sessions of SST or SD.

Subjects treated with SST increased their range of social activities, while subjects in both treatment conditions increased social contacts in comparison to subjects on the waiting-list. Between-groups analysis during a six-month follow-up was precluded due to a high number of drop-outs, although it appears that SST-treated subjects maintained their gains. Neither treatment produced significant improvement in social skills or reduction in anxiety. Furthermore, with the exception of those differences noted above, improvements found in the treated subjects were generally not reflective of improvements over and above those achieved by the wait-list group.

Trower, Yardley, Bryant, and Shaw (1978) also compared SST and SD. They specifically identified subjects as having either a social-skills deficit or excessive anxiety as their principal difficulty. Half of the identified subjects in each group were then assigned randomly to one of the two treatments, so that half of the subjects were assigned to treatments matching their deficit while the other half were in a mismatched condition. This treatment-matching appears frequently in the social phobia treatment literature.

Patients in all treatment conditions evidenced reduction in the severity of their phobias, social inadequacy, and general anxiety following treatment regardless of the specific type of deficit they exhibited. There was also some specific benefit for skill-deficit subjects treated with SST. For example, skill-deficit subjects who received SST engaged in more social activities and experienced less difficulty in social situations compared with skills-deficit patients treated with SD. No such treatment-matching advantage occurred for the primarily anxious subjects who benefited equally from both treatments.

Shaw (1979) extended the results of Trower et al. (1978) by treating 10 additional anxious subjects with imaginal flooding (repeated presentation of highly anxiety-provoking scenes to imagination). These additional subjects showed reductions in phobic severity, social inadequacy, and general anxiety similar to those attained by subjects treated with SST and SD.

Although patients treated with SST, SD, and imaginal flooding were significantly improved, the lack of a control condition in Trower et al. (1978) and Shaw (1979) is problematic. This is especially the case given the results of the study by Marzillier et al. (1976) in which treated subjects were only marginally improved over a wait-list control condition. The lack of adequate experimental control plagues several of the studies reviewed in this paper.

Öst, Jerremalm, and Johansson (1981) also employed a treatment-matching design. Thirty-two patients with social phobia were classified as either "behavioral reactors" or "physiological reactors" based upon their responses during a role-played social interaction. Physiological reactors evidenced greater cardiac reactivity during the interaction, whereas behavioral reactors evidenced greater overt signs of anxiety during the conversation. Half the subjects in each group were then assigned randomly to either SST or applied relaxation (AR). AR combines multiple relaxation procedures (see below) and was hypothesized to be a better treatment match for the physiological responders. SST was presumed to be the best treatment match for patients with disrupted behavioral responses.

There was some limited support for treatment matching in this study. Behavioral reactors treated with SST (matched condition) increased social activity and social contacts, evidenced greater improvement on self-report measures of social fear, social difficulty, and avoidance of social situations, and reported lower subjective anxiety during a behavioral test when compared with behavioral reactors treated with AR (mismatched condition). Physiological reactors participated in more social activities, made more social contacts, and evidenced fewer signs of anxiety during the behavioral test when treated with AR (matched condition) than when treated with SST (mismatched condition). Most analyses showed no differences between the matched and mismatched groups.

Mersch, Emmelkamp, Bögels, and van der Sleen (1989) used a similar treatment-matching approach to identify behavioral reactors, as defined in Öst et al. (1981), and "cognitive reactors." This latter group comprised subjects with social phobia scoring relatively lower on a measure of rational thinking. SST and rational-emotive therapy (RET; Ellis, 1962) were administered in group format to half of the subjects in each group. RET is a complex cognitive-behavioral therapy that involves the analysis and disputation of clients' irrational beliefs (Ellis, 1962). Social anxiety was reduced significantly in every condition, and there were some findings which ran counter to the treatment-matching hypothesis. For example, patients receiving SST were rated as being less anxious and more skillful on a behavioral test but also reported more positive self-statements at post-treatment. Subjects receiving RET rated themselves as more skillful and less anxious at post-treatment and six-week follow-up. There were virtually no differences between subjects in the matched and mismatched conditions. Fourteen months after treatment ended, SST and RET treated subjects maintained their within-group gains (Mersch, Emmelkamp, & Lips, 1991). There were no differences between treatment conditions or between subjects treated in the matched vs. mismatched conditions.

One study compared SST with exposure to feared social situations for the treatment of social phobia. Wlazlo, Schroeder-Hartwig, Hand, Kaiser, and Münchau (1990) compared an individually-tailored but group-administered SST program (Liberman, King, De Risi, & McCann, 1975) with individual- and group-administered exposure. Seventy-eight patients were judged retrospectively to have either a "primary social skills deficit" or a "primary social phobia." Subjects were assigned to treatments based only upon the time they applied for treatment. Thus, there was no random assignment of subjects to treatment condition, and there was no systematic matching of subject type to treatment type.

Both groups of subjects receiving SST reported reduced social anxiety, avoidance, and interference of their symptoms with daily life activities. They also evidenced reductions in depression and obsessive rumination. Similar gains were made by subjects treated in the exposure conditions, and there were few differences at either the post-treatment or three-month follow-up assessment. Although patients treated with SST made significant gains, it is difficult to determine how much of these gains should be attributed to SST or the remediation of social skills deficits since all patients were given specific instructions for exposure as part of the homework component of all treatments.

(i) Addition of other treatment components

Two studies have examined the efficacy of adding other treatment components to SST for the treatment of social phobia. Stravynski, Marks, and Yule (1992) examined the addition of cognitive modification procedures to SST in the treatment of 22 subjects meeting *DSM-III* criteria for social phobia. Subjects received 12 weekly 1.5-hour individual or group sessions (assignment to individual or group modes of treatment was not random) following a control waiting period in which all subjects received only assessments. Patients in both conditions (SST with or without cognitive modification) reported increases in degree of social interaction and reductions in depression and irrational beliefs regarding social situations following treatment. Similar results were reported at post-treatment assessment in both individual and group treatment conditions. At six-month follow-up, gains were maintained with essentially no difference between subjects in the two treatment conditions. Cognitive procedures did not produce any benefit over and above SST alone. This issue will be discussed further in Section 6.21.3.4.1(iii).

Falloon, Lloyd, and Harpin (1981) examined whether the addition of propanolol, a beta-blocker, would enhance the effects of SST for 16 subjects meeting *DSM-III* criteria for social phobia. Treatment which began after a four-week waiting period, was targeted at two problematic situations for each subject, with each problem the focus of one-half of the total treatment effort. SST began with a six-hour marathon session in which each subject met with another subject and a lay therapist focusing on the first problem situation. This was followed by two weeks of *in vivo* practice with the aid of the therapist. The focus then shifted to the second problem situation and the procedures were repeated.

No changes occurred during the pretreatment waiting period. Analyses of within-group changes showed reductions in social anxiety, decreased difficulty in targeted situations, and increases in positive self-image. A six-month follow-up of 81% of the subjects indicated that gains were maintained. There were no between-groups differences, however, indicating that propanolol did not enhance the efficacy of SST.

(ii) Recent advances

Although interest in SST had declined in recent years, it has received renewed interest as part of multicomponent treatment packages for the treatment of more severely disturbed individuals. Two studies present preliminary data on the efficacy of treatments which combine several treatment components and which prominently feature social skills training. Feske et al. (1996) used a combination of group exposure, relaxation training, systematic desensitization, and SST in the treatment of generalized social phobics with and without avoidant personality disorder. Both groups of patients improved from pretest to post-test and achieved further gains by three-month follow-up. Differences between patients with and without APD have been previously described.

Social effectiveness therapy (SET) combines education, social skills training, imaginal exposure, and therapist-directed exposure (Turner, Beidel, Cooley, Woody, & Messer, 1994). Turner et al. (1994) employed a broad set of assessments including self-report measures, a standardized behavioral test, and clinician ratings as well as a composite index of outcome (Turner, Beidel, Long, Turner, & Townsley, 1993) in an uncontrolled study of 17 patients meeting criteria for generalized social phobia. A combination of individual and group-treatment sessions were administered for 29 sessions conducted over 16 weeks. At post-treatment, 84% of the 13 patients who completed treatment (59% of the full sample) were classified as having achieved either moderate or high end-state functioning.

Turner, Beidel, and Cooley-Quille (1995) contacted patients for follow-up assessment two years after they completed SET. Eight of the original 13 patients completed a self-report battery while the remaining five completed a telephone interview. These patients maintained their gains or made some additional gains 21–24 months after the conclusion of treatment. Although these studies produced promising results, they are clearly preliminary and require follow-up evaluation in controlled treatment trials. Furthermore, they tell us little about the efficacy or mechanism of SST for social phobia.

6.21.3.2 Relaxation Techniques

The use of relaxation techniques for social phobia is based on the straightforward notion that they should provide the person with a means of coping with the physiological manifestations of anxiety. Several studies have examined the effectiveness of relaxation strategies in the treatment of social phobia. Most commonly, studies of this sort employ one of only a few strategies. In this section, we review studies that have employed either progressive muscular relaxation (Jacobson, 1938), systematic desensitization (Wolpe, 1958), or applied relaxation (Öst, 1987).

6.21.3.2.1 Review of empirical studies of relaxation techniques

Three studies already reviewed (Marzillier et al., 1976; Shaw, 1979; Trower et al., 1978) examined SD in comparison with SST and imaginal flooding. As noted, those studies found within-group improvements for SD but few group differences between SD and the other treatments. Furthermore, just one study included a control condition, and that study showed little benefit for SD above and beyond the wait-list control group (Marzillier et al.).

Two other studies compared progressive muscular relaxation to exposure techniques (Al-Kubaisy et al., 1992; Alström, Nordlund, Persson, Hårding, & Ljungqvist, 1984). In both studies (reviewed in more detail in the section on exposure techniques), relaxation fared poorly when compared with exposure.

(i) Applied relaxation

Öst and colleagues have had more success with alternative strategies employing relaxation techniques by linking relaxation more closely to actual social situations. Applied relaxation (AR) involves a series of techniques in which subjects (i) increase awareness of the earliest signs of anxiety and (ii) apply a series of relaxation techniques during anxiety-provoking situations (Öst, 1987). These techniques begin with standard progressive muscular relaxation strategies but then aim to decrease the time required to achieve a relaxed state. With practice, subjects reach moderate levels of relaxation in just 20–30 seconds. They then apply their relaxation skills, first in practice and then in real-life feared situations. These procedures have been used in two studies of patients with social phobia. Both studies used AR and a treatment-matching approach. A study described earlier indicated that physiological reactors who received AR participated in more social activities, made more social contacts, and showed fewer behavioral signs of anxiety during a social interaction test than physiological reactors who received SST (Öst et al., 1981).

Jerremalm, Jansson, and Öst (1986) used a similar strategy for physiological reactors and cognitive reactors (defined by high rates of endorsement of negative cognitions after a behavioral test), this time matching cognitive reactors with self-instructional training, a highly structured cognitive-behavioral technique. AR was more effective than a waiting-list condition and as effective as stress-inoculation training (SIT) on a number of measures. There was no support for the treatment-matching hypothesis and on some outcome measures, SIT outperformed AR for the physiological reactors as well. This study will be reviewed in more detail in Section 6.21.3.4.1.

6.21.3.3 Exposure-based Techniques

Exposure to a phobic stimulus has been the cornerstone of behavioral treatments and is viewed as a central component for effective fear reduction (Barlow & Beck, 1984). Thus, exposure has been evaluated in several studies of the treatment of social phobia. Exposure takes many forms in these studies, varying on several dimensions including degree of therapist involvement, length of exposure sessions and total exposure time in therapy, and imaginal vs. role-played vs. actual (*in vivo*) exposure, to name just a few. There is virtually no research that systematically compares the differential effects of these dimensions of exposure in the treatment of social phobia.

6.21.3.3.1 Review of empirical studies of exposure-based tehniques

Fava, Grandi, and Canestrari (1989) provided instructions for self-directed exposure to 10 social phobics in an uncontrolled study. Eight treatment sessions produced significant reductions in self-report and observer-rated anxiety in the seven patients who completed treatment. Al-Kubaisy et al. (1992) compared self-directed *in vivo* exposure with and without therapist assistance to relaxation strategies in the treatment of 28 social phobic patients (this was part of a larger study which included agoraphobic and specific phobia patients). Patients in the exposure conditions experienced greater reductions in anxiety and greater increases in approach behavior than patients treated with relaxation. Therapist-guided exposure was only minimally more effective than self-directed exposure instructions.

Alström et al. (1984) compared therapist-directed exposure to dynamically oriented supportive therapy and relaxation therapy. Forty-two patients were randomly assigned to one of the three treatments or a control condition ("basal therapy") which included unspecified anxiolytic medication plus instructions for self-exposure. Patients in the three treatment conditions also received basal therapy. Exposure patients received therapist-directed, prolonged exposure to moderately difficult but common situations. Patients were instructed to remain in feared situations until habituation occurred. Situation difficulty was graduated and therapist assistance gradually removed. Imaginal exposure supplemented this procedure for some patients treated with exposure.

Patients treated with exposure evidenced greater reductions in anticipatory anxiety and anxiety in difficult situations, avoided less when faced with difficult situations, and showed greater improvement on a measure of global disturbance compared with patients treated with relaxation or basal therapy alone. Exposure patients appeared to lose some of their gains by nine-month follow-up, no longer maintaining an advantage over patients treated with relaxation or supportive therapy. They did, however, continue to outpace patients receiving basal therapy alone on measures of situational and anticipatory anxiety.

Interpretation of the results of Alström et al. (1984) is difficult for several reasons. Patients selected for participation in this study were first deemed to be "unsuitable for insight-oriented psychotherapy" and it is unclear how this exclusion effects the generalizability of the findings. Furthermore, differences between groups at pretreatment on gender, other demographic characteristics, and level of impairment, and the unsystematic application of treatment within and across groups further compromises the reliability of these findings.

Emmelkamp, Mersch, Vissia, and van der Helm (1985) compared exposure with RET and SIT in the treatment of 34 patients meeting

DSM-III criteria for social phobia. Exposure consisted of within-session role-plays (such as public speaking and maintaining eye contact) and homework instruction to attempt *in vivo* exposure (such as making inquiries in shops and speaking to strangers). The cognitive treatments will be described in Section 6.21.3.4.1.

Exposure resulted in reductions in social anxiety and general psychopathology at post-treatment assessment and additional improvements at one-month follow-up. At post-test, exposure patients evidenced significantly greater reductions in heart rate before and after a behavior test than patients treated with RET or SIT. No other differences favored exposure at post-test or follow-up.

In a previously described treatment-matching study, Wlazlo et al. (1990) compared individual- and group-administered exposure with SST for patients classified as having primary social skills deficits or primary social phobia. Within-group changes occurred in all treatments on most measures. Patients with primary social phobia who received group exposure reported less fear of social contact and greater ability to refuse requests than patients with social skills deficits treated with group exposure. As we noted previously, problems with this study (e.g., all groups received instruction for self-exposure) compromise our ability to determine the relative benefits of these treatments.

6.21.3.4 Cognitive-behavioral Techniques

Social phobia has been a focus of attention of cognitive theorists for a considerable time. For example, Butler (1985, p. 651) asserted that patients' "thoughts and attitudes seem to play a central role in the maintenance of social phobia." Butler went on to suggest that treatment of social phobia which does not address these cognitive factors may be less effective. Several researchers have proposed models of social phobia (see earlier discussion) which highlight cognitive factors as the likely maintaining mechanism of social phobia in the face of exposure to feared situations (e.g., Clark & Wells; 1995; Rapee & Heimberg, 1997).

Cognitive-behavior therapy (CBT) draws heavily from two sources—RET, first put forth by Ellis in the early 1960s, and Beck's cognitive therapy, first put forth a decade later. Although various labels exist for what is termed CBT, most cognitive techniques share their origins and many common features with these two approaches. RET is based on the principal that human beings are prone to fall victim to one or more irrational beliefs which are common in Western civilization (Ellis, 1962). Examples include the belief that it is essential to be loved and approved by all significant people in one's life and the belief that it is necessary to be completely competent, adequate, and achieving in all areas to be worthwhile. Social phobics may easily be understood to fall victim to these two (and other) irrational beliefs. RET is designed to confront and contradict irrational beliefs through frank discussion, encouragement, and persuasion, with the ultimate goal to change a person's basic philosophy and reliance on irrational beliefs (Ellis, 1972).

Unlike RET, Beck's cognitive therapy focuses less on generalizations about one's misfortunes and more on errors of cognitive processing which lead to distortion and misinterpretation (Beck, 1976). These so-called cognitive errors include selective abstraction (focusing on a detail out of context and missing the significance of the situation) and arbitrary inference (reaching conclusions without adequate evidence or contrary to available evidence). Cognitive therapy involves openly challenging these types of errors with logic and Socratic discussion. Ultimately, patients begin to view their situation in more realistic and adaptive terms. To be precise, however, there is really no such thing as a cognitive therapy which is not also behavioral, because these therapies rely heavily on exposure to feared situations and the conduct of behavioral experiments.

6.21.3.4.1 Review of empirical studies of cognitive-behavioral technique

In a study briefly described earlier, Emmelkamp et al. (1985) compared RET and SIT with role-played and *in vivo* exposure. RET focused on challenging irrational beliefs commonly held by social phobic persons. SIT is a modified version of Meichenbaum's (1985) stress-inoculation training without relaxation procedures. SIT patients identify and record negative thoughts and affective responses that occur in social situations. Patients then work with their therapist to develop more realistic appraisals designed to increase coping with anxiety-provoking situations. Neither SIT or RET as conducted in this study included an exposure component.

Patients in the cognitive treatments reported reductions in social anxiety, general psychopathology, and irrational beliefs. RET patients reported less social anxiety on one measure at post-test and maintained this difference one month later compared with SIT patients. Additional improvement occurred in both conditions during the brief follow-up period and patients in both cognitive treatments reported fewer irrational beliefs than patients treated with exposure.

Jerremalm et al. (1986) classified 38 social phobics as physiological reactors (greater heart rate reactivity during a role-played social interaction) or as cognitive reactors (relatively greater frequency of negative thoughts during the interaction). Using a treatment-matching paradigm, patients of each type were assigned randomly to either AR, SIT, or a wait-list condition. Physiological reactors receiving either treatment were more improved than waiting-list patients on measures of anxiety and heart rate during the behavior test. Also, physiological reactors assigned to SIT reported fewer negative thoughts and more positive thoughts than the control group. Cognitive reactors receiving either treatment were also significantly improved. When treated with SIT, cognitive reactors improved more than when treated with AR on three of seven self-report measures. No advantage was found for the physiological reactors treated with AR, and on two measures, SIT was actually more effective than AR.

In another study described earlier, Mersch et al. (1989) also used a treatment matching model, comparing RET with SST in the treatment of social phobic patients classified as either cognitive or behavioral reactors. Both groups of patients evidenced numerous improvements regardless of treatment including reductions in social anxiety. Contrary to the treatment-matching hypothesis, patients treated with SST improved on measures of cognitive functioning and patients treated with RET rated themselves as more skillful.

(i) Combined cognitive-exposure techniques

Several studies have combined cognitive techniques with exposure more fully. Kanter and Goldfried (1979) first evaluated a cognitive treatment with 68 volunteers who appear to have met diagnostic criteria for social phobia (this study preceded publication of *DSM-III*). In this variation of RET known as systematic rational restructuring (SRR; Goldfried, DeCenteceo, & Weinberg, 1974), patients use imagery of anxiety-provoking situations to identify unrealistic thoughts, logically challenge those thoughts, and substitute more adaptive ones in their place. Anxiety experienced during imagery cues the patient to begin cognitive procedures. SRR was compared to self-control desensitization (SCD; Goldfried, 1971) in which patients respond to imagery-induced anxiety with progressive relaxation, to the combination of SCD and SRR, and to a wait-list control. Patients were treated in groups of 8–10 for seven weekly 1.5-hour sessions.

Patients in the three active treatments improved significantly more than waiting-list patients. Patients receiving SRR (singularly or as part of the combined treatment) showed significant improvement on social anxiety, trait anxiety, and irrational beliefs; improvement was seen on 16 of 19 measures overall. SCD treated patients improved on 10 of 19 measures. SRR patients also reported lower trait anxiety, fewer irrational beliefs, and lower anxiety during a behavior test than SCD patients. Combined treatment patients reported less anxiety about the prospect of giving a speech and less anxiety during a behavior test than SCD patients. At a nine-week follow-up assessment, patients on active treatments generally maintained their gains. Patients treated with SRR had significantly greater reductions in trait anxiety, fear of negative evaluation, and irrational beliefs than SCD patients.

Stravynski (1983) treated a single patient with psychogenic vomiting which occurred whenever the patient visited his girlfriend's parent's home and when he went to theaters and bars. *In vivo* exposure was combined with social skills training and cognitive restructuring and all components were introduced simultaneously. Vomiting was eliminated after seven sessions, and anxiety in three of four target situations dramatically decreased. Seven months following treatment the patient continued to perform the target behaviors, and an informal follow-up after two years suggested that gains had been maintained. In an uncontrolled study, Mersch, Hildebrand, Lavy, Wessel, and van Hout (1992) administered a unique combination of RET and paradoxical interventions to three patients with fears that public embarrassment would result from the occurrence of their physiological symptoms of anxiety (e.g., blushing, sweating, trembling). Paradoxical techniques incorporated exposure. All patients improved on a broad array of measures and frequency of feared symptoms was reduced, although anxiety experienced on occurrence of these symptoms remained high. While these gains were maintained at an 18-month follow-up, methodological considerations limit conclusions about the efficacy of this treatment approach.

Heimberg, Becker, Goldfinger, and Vermilyea (1985) treated seven social phobic patients in small groups with a combination of cognitive restructuring, imaginal exposure, exposure to simulated social situations, and homework assignments for *in vivo* exposure. Cognitive restructuring was conducted immediately following exposure exercises and focused on negative cognitions related to the simulated or imagined situation. These procedures resulted in significant reductions in social anxiety, general anxiety, and fear of negative evaluation immediately following treatment. Patients rated their own performance during a behavior test as higher in quality, and they were rated by others as less anxious. Attributions for negative outcomes became less internal and stable. For six of the seven patients, gains were maintained at a six-month follow-up on both self-report and behavior test measures, whereas one patient's anxiety returned to baseline levels.

Based on this preliminary study, Heimberg et al. (1990) removed imaginal exposure and developed a more highly integrated treatment combining cognitive restructuring and exposure exercises. In this treatment package, referred to as cognitive behavioral group therapy for social phobia (CBGT), cognitive restructuring is employed before, during, and after simulated and *in vivo* exposures (the latter comprise homework assignments). CBGT is described in more detail by Heimberg et al. (1995).

Heimberg et al. (1990) compared CBGT with an attention-placebo group in the treatment of 49 social phobic patients. The comparison treatment combined educational presentations on topics relevant to social phobia and guided peer support. Patients were assigned randomly to either CBGT or the placebo group. At post-test, patients treated with CBGT were less anxious during a behavior test and were rated as less severely impaired by clinical assessors. CBGT patients maintained their gains at a six-month follow-up and reported more positive and fewer negative thoughts during the behavior test. Eighty-one percent of CBGT patients, compared with 47% of placebo patients, were rated as having made clinically significant improvement at follow-up.

Heimberg, Salzman, Holt, and Blendell (1993) reassessed 19 of the patients who participated in the Heimberg et al. (1990) study an average of 5.5 years following treatment (range 4.5–6.25 years). Although these patients were less impaired at pretest than patients who did not participate in this follow-up, there were no differences between participating CBGT and control patients. Nonetheless, generalizations based on these results should be limited to less impaired patient populations.

Within these limits, this study supports the long-term efficacy of CBGT. Specifically, CBGT patients were rated by independent assessors as less severely impaired and as experiencing less interference at work, in social activities, and in their family life compared with attention-placebo patients. Eighty-nine percent of CBGT patients and 44% of placebo patients were judged to be significantly improved. CBGT patients were also rated as evidencing more social skills and less anxiety during a behavioral test.

(ii) Cognitive-behavioral techniques and pharmacotherapy

Several pharmacological treatments of social phobia exist and have been studied to varying degrees. Although pharmacological approaches will not be reviewed here (see Liebowitz & Marshall, 1995; Potts & Davidson, 1995, for reviews of pharmacological treatments), three studies have compared cognitive restructuring plus exposure with pharmacological treatments. Two of those studies used Heimberg's CBGT. Gelernter et al. (1991) compared CBGT with the monoamine oxidase inhibitor phenelzine, the triazolobenzodiazepine alprazolam, and pill placebo. Patients assigned to receive medication or placebo were also provided with self-exposure instructions, a procedure that makes this study more clinically relevant but reduces the distinctiveness of treatments. Patients in all four groups experienced significant improvement on all measures, with few differential effects. Patients treated with phenelzine were more improved than other patients on a measure of trait anxiety at two-month follow-up, but similarities among outcomes far outweighed differences. At follow-up, patients receiving phenelzine or CBGT maintained their gains while alprazolam patients did not. Several methodological concerns complicate interpretation of these results. These include sole reliance on self-report measures, the inclusion of self-exposure instructions in the medication and placebo conditions, and an increase in the recommended number of patients in each CBGT group from six to 10.

A large-scale, multisite collaborative study compared CBGT, phenelzine, pill placebo, and the attention-placebo treatment employed by Heimberg et al. (1990). Heimberg et al. (1997) randomly assigned 133 patients to 12 weeks of one of the four treatments. Patients judged to be responders to CBGT or phenelzine continued for an additional six months of therapy with reduced (monthly) contact and six months of treatment-free follow-up. CBGT and phenelzine produced equivalent response rates, superior to both control conditions, after 12 weeks of treatment. Phenelzine led to faster response and was somewhat more effective than CBGT on some measures after 12 weeks. During the six-month untreated follow-up, CBGT patients were less likely to relapse than patients treated with phenelzine (Liebowitz et al., 1997). This was especially the case for patients with generalized social phobia. A study examining the efficacy of the combination of these two treatment modalities is underway.

The third study comparing pharmacological treatments with cognitive restructuring and exposure treated 34 musicians with performance anxiety (Clark & Agras, 1991). The combination of cognitive restructuring, exposure, and relaxation was evaluated with and without the anxiolytic medication buspirone. Musicians were randomly assigned to one of four conditions: cognitive-behavioral treatment with buspirone, cognitive-behavioral treatment with placebo, buspirone alone, and placebo alone. Generally, patients treated with cognitive-behavioral therapy experienced improvement on several important outcome variables, whereas buspirone was no more effective than placebo. Cognitive-behavioral therapy plus placebo was the most effective treatment combination, and these patients outperformed all others on a measure of confidence in performing at a one-month follow-up assessment.

(iii) Component analysis of cognitive-exposure techniques

From this review, it is clear that the combination of cognitive restructuring and exposure can be a highly effective treatment for social phobia. However, these studies do not tell us whether or not it is necessary to combine these two treatment approaches and whether the addition of cognitive restructuring to exposure techniques is in any way more effective than exposure alone. A series of studies has examined this issue and is reviewed below.

Butler, Cullington, Munby, Amies, and Gelder (1984) compared exposure only with exposure plus anxiety management training (Suinn & Richardson, 1971). The latter comprises relaxation, distraction, and rational self-talk. Patients in the exposure-only condition received a filler treatment which occupied the same amount of time as anxiety management training. After treatment, patients in both exposure conditions were superior to a wait-list group, having achieved reductions in phobic severity, anxiety during a behavior test, difficulty during social situations, general anxiety and depression. Combined treatment patients achieved lower scores on two measures of social anxiety compared with patients receiving exposure only.

Differences between combined treatment patients and exposure-only patients were maintained or increased at a six-month follow-up assessment. Fully 40% of patients receiving exposure only sought further treatment in the following 12 months, whereas no combined treatment patient did so. Although anxiety management training is not a solely cognitive intervention, *post hoc* analyses suggested that rational self-talk was the most frequently utilized coping technique. Problems with procedures in the exposure condition are elaborated elsewhere (Juster, Heimberg, & Holt, 1996) but include limitation on the total time spent on exposure and its procedures, and low credibility ratings for the exposure-only condition possibly due, in part, to the filler treatment.

Mattick and his colleagues conducted two studies examining exposure and cognitive techniques in various combinations (Mattick & Peters, 1988; Mattick, Peters, & Clarke, 1989). The first study compared therapist-assisted exposure with and without cognitive restructuring (Mattick & Peters, 1988). In contrast with the study by Butler et al. (1984), no filler treatment was used. Both treatments yielded similar post-treatment outcomes, including reductions in avoidance, phobic severity, and depression. At three-month follow-up, patients in the combined treatment group completed a greater percentage of tasks during a behavioral test and evidenced lower avoidance and higher scores on composite measures of improvement and end-state functioning than patients treated with exposure alone.

In their second study, Mattick et al. (1989) compared the same conditions as in the previous study, but added a cognitive restructuring only condition and a wait-list condition. Patients in the three active treatments completed more tasks during a behavior test and scored lower on self-report measures of phobia severity and avoidance than patients on the wait-list. Exposure only and the combined treatment were more effective than cognitive restructuring alone in terms of the tasks completed during the behavior test. At the three-month follow-up, however, patients in the cognitive restructuring only and combined treatment conditions continued to improve, whereas patients receiving exposure only appeared to deteriorate. Patients in the combined treatment condition experienced the greatest improvement on percentage of behavioral tasks completed.

Not all studies support the combination of exposure and cognitive techniques. In fact, the majority of studies on this issue do not support the need for cognitive procedures to be added to exposure techniques. Biran, Augusto, and Wilson (1981) examined the effect of adding cognitive therapy to *in vivo* exposure in a multiple-baseline-across-subjects design. Two of three women with fears of writing in public received five sessions of cognitive restructuring followed by five sessions of exposure. The third patient received exposure only. Exposure, conducted according to a standardized hierarchy of feared writing situations, produced significant increases in the number of writing tasks performed. Cognitive restructuring did not enhance the effectiveness of exposure. However, reductions in fear ratings during performance of the exposure situations were less clearly tied to specific treatment.

At nine-month follow-up, avoidance of feared situations remained low. However, fear in those situations returned to pretreatment levels. Although no further follow-up was conducted, one might speculate that this desynchrony between approach behavior and anxiety could predict poor long-term outcome. In fact, two of the three patients sought additional treatment during follow-up, one for unspecified "social issues," the other for further anxiety reduction. All three indicated some disappointment that their anxiety reduction had not been maintained. Although this study has been criticized for several reasons, probably the most critical concern involves the total segregation of treatment components in a manner inconsistent with clinical practice and which may reduce treatment effectiveness (Heimberg, 1989; Heimberg, Dodge, & Becker, 1987).

More recently, Taylor et al. (1997) randomly assigned 65 patients to eight sessions of cognitive restructuring without exposure or eight sessions of the filler treatment used by Butler et al. (1984). Cognitive restructuring was clearly more effective than the filler condition after this initial phase of treatment. Following an assessment, both groups received additional sessions of exposure to determine if treatment response would be facilitated. There were no differences between groups after exposure on a battery of self-report measures administered at the three-month follow-up. Thus, after both groups were treated with exposure, patients who received the filler treatment were as improved as patients who had previously received cognitive restructuring.

Hope, Heimberg, and Bruch (1995a) compared exposure alone with the complete CBGT protocol described earlier to determine the relative importance of the cognitive component. Both conditions were more effective than a wait-list condition after 12 weeks of treatment. Patients treated with CBGT reported less anxiety during an individualized behavior test at post-treatment, but this was the only measure in which the full protocol outperformed exposure alone. Differences between exposure and CBGT at post-treatment, most of which favored exposure, disappeared at the six-month follow-up, at which time the two treatments were equally effective. In this trial, however, CBGT was less effective than in other studies of this protocol.

Three studies employed RET in assessing the efficacy of cognitive therapy with and without exposure techniques. Scholing and Emmelkamp (1993a) treated 30 social phobics with primary fears of blushing, sweating, or trembling. Individual treatment was administered in two four-week blocks separated by a four-week period of no treatment. Patients were randomly assigned to either *in vivo* exposure followed by RET, RET followed by *in vivo* exposure, or integrated RET and *in vivo* exposure. It is important to note that in the integrated treatment, exposures were never conducted during the therapy session. Thus, the primary focus of integrated therapy sessions was on changing irrational beliefs relative to situations which would then be the focus of home-based exposure exercises. All treatments produced substantial and equal improvements on composite measures of avoidance of target situations, irrational cognitions, and somatic complaints. No differences were evident after three-month follow-up.

Scholing and Emmelkamp (1993b) conducted an essentially similar study with 73 generalized social phobics. Patients were randomly assigned to exposure only, exposure followed by RET, or integrated RET and exposure. Treatments were provided in blocks as in the previous study and included both individual and group modalities. Patients assigned to integrated treatment in the individual modality had no exposures during their sessions. Patients assigned to exposure or integrated RET and exposure in the group modality received exposure during sessions, although discussion of maladaptive cognitions was clearly the primary emphasis in the integrated treatment. Patients in the integrated treatment reported more somatic complaints than patients in the other two treatments after the first treatment block. No significant differences were found between treatments after the second block or at three-month follow-up. Importantly, fully 47% of the exposure-only patients and 28% of the RET-followed-by-exposure patients sought additional treatment in the 18 months following their participation (Scholing & Emmelkamp, 1996). Only 6% of the patients in the integrated treatment condition sought further treatment during this period. While the authors reported no statistical analysis of this finding, it is similar to that reported by Butler et al. (1984).

Mersch (1995) compared exposure alone with an integrated treatment combining *in vivo* exposure, RET, and social skills training. As in the individual treatments administered by Scholing and Emmelkamp (1993a, 1993b), no exposures were conducted during treatment sessions. Thirty-four patients were randomly assigned to either a wait-list control group or to one of the two treatment groups. Sixteen sessions of individual therapy were provided, and follow-up assessments were conducted at three months and 18 months. Both treatments were superior to the wait-list control at post-test, but there were no differences between exposure alone and the integrated treatment. At 18-month follow-up, patients in both active treatments achieved additional gains on self-report measures of social anxiety, but they still did not differ from each other.

(iv) Results of meta-analyses

An alternative method of examining the relative importance of treatment components is meta-analysis, a technique which compares averaged effect sizes for particular treatments or treatment components across several studies. Three meta-analyses examining cognitive-behavioral treatment of social phobia have been conducted (Feske & Chambless, 1995; Gould, Buckminister, Pollack, Otto, & Yap, 1997; Taylor, 1996). In the meta-analysis by Feske and Chambless (1995), exposure plus cognitive restructuring and exposure alone did not differ in dropout rates and yielded similar effect sizes on both post-treatment and follow-up measures of social anxiety, cognitive symptoms, and depression/anxiety. Gould et al. (1997) evaluated 24 studies which examined cognitive-behavioral and pharmacological therapies which included a control condition. CBT and pharmacological treatment produced similar effect sizes for reductions in social anxiety, and both effect sizes were significantly different from zero. Within CBT, exposure with cognitive restructuring and exposure alone yielded similar attrition rates and effect sizes. Lastly, Taylor (1996) examined 42 treatment studies and compared six conditions: waiting-list control, placebo (the combination of pill placebo and attention-placebo), exposure alone, cognitive restructuring without exposure, cognitive restructuring with exposure, and SST. The dropout rate did not differ across the six conditions. The four active therapies and placebo produced greater effect sizes than the waiting-list control; however, only cognitive restructuring with exposure had a significantly larger effect size than placebo. Effects remained stable during follow-up for all treatments.

(v) Summary

The study of the relative efficacy of exposure vs. combined cognitive restructuring plus exposure represents one of the critical issues in the treatment of social phobia. However, this collection of studies presents results that are contradictory, confusing, and difficult to interpret. Several studies did not support the need for the integration of exposure and cognitive restructuring, while others suggest that combined treatment is superior and that additional gains are more likely during the follow-up period. The meta-analyses produced contradictory results regarding this question as well. Thus, the question of the importance of the integration of exposure and cognitive restructuring in the treatment of social phobia remains unresolved. However, cognitive change may be central to good clinical outcomes, regardless of how it is produced. The importance of cognitive change is demonstrated by studies in which change in fear of negative evaluation from pretreatment to post-treatment predicts end-state functioning (Mattick & Peters, 1988; Mattick et al., 1989). However, cognitive interventions may not be necessary to engender cognitive change. Exposure alone may provide sufficient disconfirmatory information to alter dysfunctional beliefs (Hope et al., 1995a; Mattick & Peters, 1988; Newman, Hofmann, Trabert, Roth, & Taylor, 1994).

Turk, Fresco, and Heimberg (in press) outline several additional issues that should be considered before conclusions are drawn regarding the necessity of cognitive interventions and the role of cognitive change in successful treatment outcome. The first issue concerns the measures used to demonstrate cognitive change. Questionnaire measures commonly used to assess cognition correlate highly with social phobia symptom measures. When change is noted on these measures, the observed gains may be a product of change in the portion of variance shared with symptom measures. In other words, change on commonly used questionnaire measures of cognition may reflect changes in cognition, anxiety, or both (Heimberg, 1994). Second, many “purely behavioral” interventions may implement “exposure only” procedures in a manner which facilitates cognitive change (Newman et al., 1994). Specifically, “exposure only” treatments which include therapist and/or group member feedback regarding patient skill, visibility of anxiety symptoms, ability to cope with anxiety, etc., share many features with cognitive approaches, although these aspects of therapy may not be labeled as cognitive interventions by noncognitive therapists. Finally, while studies that find equivalent outcomes for exposure vs. exposure plus cognitive restructuring typically interpret this pattern to mean that cognitive restructuring does not add to the efficacy of exposure, alternative interpretations are available. It is also reasonable to suggest that cognitive restructuring activities reduce the amount of exposure necessary for effective treatment.

6.21.3.5 Psychodynamic Formulations

Little has been written about the psychodynamic perspective on social phobia, and even less research specifically testing psychodynamic assumptions has been conducted. Still, psychodynamic theory and therapy remain popular and merit some discussion here. Gabbard (1992) proposes a traditional psychodynamic conception of social phobia. In one formulation, social interaction characterized by anxiety and withdrawal are presumed to be manifestations of important early developmental events re-experienced as adult anxiety symptoms. Specifically, it is thought that some social phobics have an unconscious wish to be the center of attention and to receive positive affirmation by those in their environment. This wish produces an immediate shame reaction in the social phobic individual believed to be associated with early negative shame-producing experiences with disapproving parental figures. Social phobia is also thought by some to be related to separation anxiety. In this variation, social phobia is seen as a recapitulation of childhood struggles with individuation and attachment. Efforts to become increasingly autonomous are countered by fears of losing parental love. According to Gabbard (1992), certain characteristic internal representations are common to psychodynamic views of social anxiety including criticism, ridicule, humiliation, abandonment, and embarrassment associated with parents, caregivers, and siblings. These so-called introjects are projected onto others in the social phobic person's environment and become the object of his/her adult anxiety.

In contrast to the more traditional psychodynamic perspective of social phobia, Cloitre and Shear (1995) espouse a psychobiological model which draws heavily on ethological theory, especially the work of Trower and Gilbert (1989). This model posits that competitive and cooperative modes of relating which are important to many species are central to human social interaction as well. Specifically, a competitive or defensive system of interaction is characteristic in groups that develop dominance hierarchies. Submission and dominance are critical behaviors that maintain the organization's hierarchical structure. A cooperative or safety system allows sharing of resources and effort, minimizing differences between members of the group. Hierarchies are more horizontal in a cooperative mode and more vertical in a competitive mode. Applied to social phobia, it is hypothesized that the person with social phobia is overly reliant on the defensive/competitive system of relating, always treating social interaction situations as dominant–submissive in nature (with the social phobic individual usually taking on a submissive role but desperately wanting to be the dominant figure). This bias towards a defensive posture leads the social phobic individual to become hypervigilant for threat cues in others' behavior, to be overly competitive or overly submissive, and to become hypersensitive to criticism. Although both the competitive and cooperative systems may be adaptive in different situations, social interaction is typically cooperative. Similar to Gabbard's (1992) perspective, it is believed that early interaction with parental figures stimulates overuse of the defensive system. In particular, parents may focus the child's attention on "dangers" in the social environment or conversely overprotect them unnecessarily. Children may experience their parents as controlling, hostile, or rejecting, and parents may communicate that caring is contingent on certain behaviors such as a submissive attitude with parents. Although some research does support early experiences as potential progenitors of later social anxiety in adult social phobics, this does not necessarily provide support for other aspects of these psychodynamic formulations.

6.21.4 PREDICTORS OF OUTCOME

Although there are now effective treatments for social phobia, not everyone who receives treatment benefits from it. For example, Heimberg et al. (1997) reported that 75% of patients who completed a 12-week trial of CBGT were independently judged to be moderate or full responders to that treatment. These figures are reduced (58%) when drop-outs are considered in an intent-to-treat analysis. Clearly, many patients with social phobia do not benefit maximally from the treatments they receive. It is not known whether patients who fail to respond to one treatment might be likely to respond to a different treatment, nor is it known which patient characteristics might predispose toward better or worse response to one or another treatment. However, several studies have begun to examine this issue. The majority of these studies have attempted to identify predictors of response to Heimberg's CBGT (Brown et al., 1995; Chambless, Tran, & Glass, 1997; Holt, Heimberg, & Hope, 1989, 1990; Hope et al., 1995b; Juster, Heimberg, & Mattia, 1993), whereas one other study examined predictors of response to flooding (Turner, Beidel, Wolff, Spaulding, & Jacob, 1996). It is not known how these results might generalize to the prediction of outcome of other treatments.

Demographic factors have shown little consistency in the prediction of outcome of cognitive-behavioral therapy for social phobia. Factors such as age, gender, marital status, employment, and educational status have been unrelated to outcome (Holt et al., 1989, 1990; Juster et al., 1993). Holt et al. (1989) found age of onset, locus of fear, and lower scores on the Beck Depression Inventory (BDI; Beck, Ward, Mendelson, Mock, & Erbaugh, 1961) to predict outcome. Specifically, later onset, public speaking vs. social interaction fears and lower BDI scores were associated with better outcomes. However, Holt et al. (1990) found that similar results all but disappeared when pretreatment social phobia severity was statistically controlled. Juster et al. (1993) found no relationship between demographic factors, pretreatment clinical measures of social anxiety and depression, locus of control or general anxiety and response to CBGT.

Several studies have examined social phobia subtype as a potential predictor of CBGT outcome. Two studies found that patients with generalized social phobia improved with treatment as much as patients with nongeneralized social phobics. However, because they came to treatment more impaired than nongeneralized social phobics, they remained more impaired after treatment (Brown et al., 1995; Hope et al., 1995b). Patients with generalized social phobia were less likely to achieve high levels of endstate functioning than patients with nongeneralized social phobia. Heimberg et al. (1997) reported essentially the same pattern of results.

Turner et al. (1996) found that generalized and specific social phobics experienced similar levels of distress and habituation in response to flooding techniques. Moreover, measures of endstate functioning showed a similar pattern of response to that reported above for CBGT. Specifically, generalized social phobics' response to flooding was similar to the response of specific social phobics, but because they began treatment more impaired, they finished treatment that way as well. Subtype differences in response to treatment appear to reflect, for the most part, differences in severity.

The effect of APD diagnosis on outcome of the treatment of social phobia was addressed in Section 6.21.1.5. To summarize, generalized social phobics with and without APD show similar effects from cognitive-behavioral therapy. The presence of APD before treatment predicts lower endstate functioning after treatment, but as for social phobia subtype, this is related to pretreatment severity.

Patient expectancy regarding the benefits to be obtained from treatment may contribute to the outcome of cognitive-behavioral treatment of social phobia, and two studies have examined the expectancies of patients treated with CBGT (Chambless et al., 1997; Safren, Heimberg, & Juster, 1997). Both studies found expectancy to be a unique predictor of outcome even when other important variables were controlled. For example, Chambless et al. found that higher expectancies at the beginning of treatment were associated with improvement on self-ratings of anxiety and skill even after removing the effect of depression. Similarly, Safren et al. found that expectancy was significantly associated with improvement on a variety of self-report and interviewer measures of psychopathology after controlling for pretreatment severity. Thus, patient expectancies regarding the likelihood of obtaining benefit are a unique predictor of outcome. As noted by Chambless et al., the mechanism by which expectancies are associated with outcome is unknown and not necessarily causal.

6.21.5 SUMMARY AND FUTURE DIRECTIONS

Social phobia, described as the neglected anxiety disorder just 13 years ago (Liebowitz et al., 1985), has become an important focus of the attention of clinical psychologists and other mental-health professionals. The focus of this research has been on developing effective treatments as well as trying to better understand the phenomenology of social phobia. In this chapter, an overview of that effort has been provided. It is known, for example, that social phobia is more common than once believed, affecting nearly 8% of the US population in a given year. Social phobia affects more women than men; however, men and women seek treatment for social phobia in approximately equal numbers. Onset of the disorder is usually early in life, beginning for some in childhood, while for many, it may not appear until their teens or early 20s. Evidence points to social phobia as a chronic condition when left untreated, and it is not uncommon for patients to wait many years before pursuing treatment. Impairment in functioning due to social phobia may be extensive, reducing occupational and educational attainment in addition to social functioning. Finally, social phobia is usually associated with one or more comorbid conditions, especially other anxiety and mood disorders. Alcohol, drug abuse, and Axis II disorders are common complications of social phobia.

The serious nature of social phobia underscores the critical need for effective treatments for this disorder. In this chapter, the principal psychosocial treatment approaches for social phobia have been reviewed. These included

SST, relaxation techniques, exposure, and various cognitive-behavioral techniques. Patients treated with social skills training appear to achieve and maintain gains following treatment. However, as noted elsewhere, the lack of well-controlled treatment trials of SST reduces our ability to make strong statements about its efficacy (Juster & Heimberg, 1995). Despite this, SST may be an important ingredient in treatment of the most difficult patients with social phobia, especially those who also meet criteria for APD. The efficacy of this approach awaits further investigation.

Relaxation techniques have had mixed success in alleviating social phobia. Some studies found relaxation to be better than a wait-list condition, while others have not. Öst has reported more consistently positive results for AR, a combination of relaxation and exposure procedures which appears to benefit some patients with social phobia. However, AR procedures did less well than cognitive treatments in another study.

Exposure has fared well as a treatment for social phobia. However, as with SST, methodological problems limit conclusions about the comparative efficacy of exposure and other techniques. The bulk of studies reviewed combined exposure with some form of cognitive therapy, and several of these were methodologically sophisticated studies which allowed strong inference. These studies demonstrated that exposure plus cognitive restructuring is an effective treatment for social phobia, resulting in significant within-group gains and surpassing the performance of attention-placebo control conditions. CBGT, in particular, has demonstrated long-term efficacy as well. Despite these positive results, other studies which examined the components of cognitive restructuring and exposure separately and in combination have yielded conflicting and contradictory findings. Some studies support the combination of exposure and cognitive restructuring as superior, whereas others fail to show that the combined approach is better. Three meta-analyses also provide equivocal evidence for the utility of combining exposure and cognitive restructuring. Future studies are needed to address this issue further, paying special attention to methodological and conceptual issues raised herein.

The distinction between efficacy and effectiveness has become a central point of discussion (Seligman, 1995; VandenBos, 1996). Efficacy studies determine treatment response under relatively strict laboratory conditions. These conditions include the use of control groups or comparative treatments, random assignment, manualized treatments, a fixed number of sessions, raters who remain uninformed as to treatment assignment, patients with few or no comorbid conditions, and a fixed follow-up period (Seligman, 1995). The studies reviewed in this chapter are all studies of efficacy. In contrast, effectiveness studies establish a treatment's utility under real-world conditions in which one and usually several of the conditions of efficacy studies are not met. Effectiveness studies make sense once efficacy studies establish the empirical validity of a treatment. Thus, the effectiveness of combined exposure and cognitive restructuring for social phobia appears to be a timely issue.

One difficulty with efficacy studies is that the sample of patients who enter a study represents a narrow sampling of the population of patients with the disorder. Patients are often excluded from efficacy studies (e.g., due to the presence of comorbid conditions) or they may decline to participate in a study because of concern over random assignment, assignment to a placebo condition, etc. The question remains whether or not patients who are treated in an efficacy study respond similarly or differently to the treatment than patients who decide not to participate or are excluded from participation. These latter groups may represent a substantial portion of the population of patients with the disorder (perhaps the majority) but are often not represented in samples of patients for whom a treatment may be validated. One study of social phobia has addressed this issue. Juster, Heimberg, and Engleberg (1995) examined subjects screened for participation in Heimberg et al.'s (1997) comparative treatment trial of CBGT and phenelzine described earlier. One group of subjects was excluded for medical or diagnostic reasons and another refused entry in to the study, citing concerns about the side effects of phenelzine as the primary reason. The remaining subjects were treated in the comparative outcome study. Subjects who refused and were excluded from the trial were treated with CBGT outside the controlled trial, partly in an effort to establish the effectiveness of CBGT for a broader set of patients with social phobia. The three groups differed somewhat on demographic variables including measures of socioeconomic status and social support. Despite these differences, the three groups of patients demonstrated comparable gains in CBGT, suggesting that results of the clinical trial may be extended to these other groups of patients.

The Juster et al. (1995) study only begins to examine the effectiveness of CBGT and similar treatments for social phobia. Further research is needed to establish the effectiveness of these techniques outside university research centers and under less well-controlled conditions. Also, patients currently served by these centers tend to be more homogeneous than the broader population of social phobics. Treatment trials in nontraditional settings serving a diversity of patients need to be conducted. As we have noted before, the development of more effective approaches for the subset of patients who do not benefit from current methods is crucial (Juster & Heimberg, 1995). Whether that be in longer trials of existing treatments, combined pharmacotherapy and psychotherapy, or as yet untested treatment methods (e.g., interpersonal psychotherapy), there remains a proportion of patients who obtain little or no benefit from current treatments. Creative adjuncts to current treatments should also be considered and studied further. For example, the use of videotaped feedback appears to be a particularly useful therapeutic intervention in socially anxious subjects (Rapee & Hayman, 1996) and in patients with social phobia (Flynn, Polland, Carmin, & Logan, 1994), yet these methods have not been systematically studied. The search for efficacious and effective treatments for social phobia continues to be an important research agenda.

6.22.1 DEFINITIONS

Post-traumatic stress disorder (PTSD) is an anxiety disorder that consists of a sustained and dysfunctional emotional reaction to an extreme stressor. The revised third edition of the *Diagnostic and statistical manual of mental disorders* (*DSM-III-R*; American Psychiatric Association [APA], 1987) defined a trauma as an event that is outside the range of normal human experience and that would be markedly distressing to almost anyone. However, a normative definition of a trauma proved inadequate as epidemiological studies found high prevalence rates of traumatic experiences in segments of the general population (e.g., Resnick, Kilpatrick, Dansky, Saunders, & Best, 1993). Therefore, in *DSM-IV* (APA, 1994) the criteria were modified to include two aspects: the objective characteristics of the stressor, and the subjective experiences of the victim. Specifically, the traumatized person must have experienced or witnessed a situation involving actual or threatened bodily injury or death, or threat to physical integrity, and must have felt helpless, horrified, or terrified during the experience.

According to *DSM-IV*, PTSD symptoms fall into three general clusters: re-experiencing, avoidance, and arousal. To be eligible for a diagnosis of PTSD, three criteria must be met. First, the individual must re-experience the trauma in one of the following ways: nightmares, flashbacks, intrusive thoughts, and emotional distress or physiological arousal in response to internal or external cues that serve as reminders of the trauma. Second, the individual must have at least three avoidance symptoms: avoidance of thinking about the trauma, avoidance of reminders of the event, emotional numbing, detachment or distance from other people, less interest in activities, psychogenic amnesia, or a sense of a foreshortened future. Finally, individuals must experience at least two of the following arousal symptoms: sleep disturbance, hypervigilance, exaggerated startle response, irritability or outbursts of anger, or difficulty concentrating. If these symptoms persist for at least one month and cause considerable impairment in daily living, a diagnosis of PTSD is appropriate. In addition to the anxiety symptoms of PTSD itself, there is also high comorbidity between PTSD and depressive symptoms, other anxiety disorders, and substance abuse (Kessler, Sonnega, Bromet, Hughes, & Nelson, 1995), and these can exacerbate dysfunction in daily living.

Although PTSD cannot be formally diagnosed unless symptoms persist for at least one month, many individuals show marked symptoms and impairment beginning immediately after a trauma and may benefit from some psychological intervention. Interest in this initial reaction to trauma gave impetus to the introduction of a new disorder called "acute stress disorder" into *DSM-IV* (APA, 1994). This disorder includes symptoms of PTSD with a special emphasis on dissociative symptoms and lasts anywhere from two days to four weeks post-trauma.

6.22.2 SCOPE OF THE PROBLEM

Both the prevalence of traumatic experiences and the rate of PTSD are alarming. Approximately 39% of people in the USA have experienced at least one traumatic event in their lifetime. Lifetime prevalence of PTSD is estimated at 24% among trauma victims and at 9% in the general population, with up to a third (3.4%) of these cases having chronic PTSD (Breslau, Davis, Andreski, & Peterson, 1991). In addition to individuals who meet full criteria for PTSD, up to 15% of the general population suffer from subthreshold symptoms (Davidson, Hughes, Blazer, & George, 1991).

Women appear to be somewhat more likely than men to develop PTSD following trauma (10.4% and 5%, respectively; Kessler et al., 1995). In a national sample of women, 69% had experienced some type of trauma, and 36% had been victims of crime: sexual assault, aggravated assault, or the homicide of a close friend or relative. The lifetime prevalence of PTSD in this sample was 12.9%, with six month prevalence of 4.6% (Resnick et al., 1993).

The experience of trauma according to *DSM-IV* includes not only the direct experience of a trauma, but also witnessing or learning about a traumatic event (APA, 1994). Symptoms can therefore develop in those who have little or no direct exposure to the trauma, although the symptom severity is directly related to degree of exposure (March, 1992). For example, ferry workers who were *not* among the crew of the capsized *Herald of Free Enterprise* ferry manifested PTSD symptoms, presumably because they identified strongly with co-workers who were in the ferry disaster (Dixon, Rehling, & Shiwach, 1993). This phenomenon has been referred to as the "ripples outward" effect.

Certain professionals are at risk for PTSD by virtue of increased probability of repeated direct exposure to trauma. In one study, 26% of police officers reported symptoms severe enough to meet symptom criteria of PTSD (Martin, McKean, & Veltkamp, 1986). Firefighters, emergency medical technicians, emergency room staff, and disaster workers are also thought to be at risk. For example 30% of firefighters of an Australian bushfire had chronic PTSD 29 months after the event (McFarlane, 1989).

6.22.3 RISK FACTORS FOR CHRONIC POST-TRAUMA PSYCHOPATHOLOGY

Factors related to risk of developing chronic disturbance may be divided into three types: pretrauma factors, factors related to the trauma itself, and post-trauma factors. We will briefly review research relevant to each of these factors.

Research on demographic variables has not identified reliable predictors of who will develop chronic PTSD (e.g., Foa & Riggs, 1993; Green, 1994). In contrast, it appears that poor psychological and social functioning prior to the trauma renders the individual vulnerable to developing chronic disturbances (Ruch & Leon, 1983). Also, a history of prior traumatic events in childhood or adulthood augments the response to subsequent traumas (Ellis, Atkeson, & Calhoun, 1981; Riggs, Foa, Rothbaum, & Murdock, 1992; Roth, Waylan, & Woolsey, 1990; Ruch & Leon, 1983).

It is safe to state that traumas differ in their likelihood of producing PTSD. In a retrospective study mentioned earlier, Resnick et al. (1993) found that 17.8% of female victims of aggravated assault and 12.4% of rape victims had current PTSD. In contrast, only 3.4% of female victims of noncrime trauma had PTSD. Three prospective studies of female victims of rape and nonsexual assault revealed higher rates of PTSD among the former at each data point up to three month postassault (Jaycox et al., 1996; Riggs, Rothbaum, & Foa, 1995; Rothbaum, Foa, Riggs, Murdock, & Walsh, 1992). The severity of the trauma also appears to influence subsequent severity of PTSD: the degree of combat exposure among Vietnam veterans predicted pathology (Foy, Sipprelle, Rueger, & Carroll, 1984; Pitman, Altman, & Macklin, 1989), and the perception of imminent life threat appears to predict post-trauma pathology among rape victims (Girelli, Resick, Marhoefer-Dvorak, & Hutter, 1986; Kilpatrick et al., 1989; Resick, 1986).

Just as traumas differ in their likelihood to produce PTSD, so do individuals differ in their reaction to a traumatic experience. Several post-trauma factors have been found to exacerbate symptoms. Dissociative experiences during the traumatic encounter or immediately after have been found to predict later distress or PTSD (e.g., Bremner et al., 1992; Koopman, Classen, & Spiegel, 1994; Marmar et al., 1994, Nishith, Mechanic, Griffin, & Resick, 1995; Tichenor, Marmar, Weiss, Metzler, & Ronfeldt, 1996). Also, on average, assault victims who exhibit more severe initial reactions to the trauma evidence more symptoms later on (Perry, DiFede, Musgni, Frances, & Jacobsberg, 1992; Riggs et al., 1995; Rothbaum et al., 1992; Shalev, Peri, Canetti, & Schreiber, 1996) although delayed peak PTSD symptoms were associated with more severe pathology compared with early peak (Gilboa & Foa, 1997). Evidence on the role of social support as facilitating or hindering recovery is equivocal. Indeed, empirical studies indicate that negative social interactions (e.g., victim blame or disbelief) have strong negative effects on victim adjustment, whereas positive reactions from others have little impact on adjustment (Davis, Brickman, & Baker, 1991; Ullman, 1995). Excessive anger or guilt following the trauma also appear to block readjustment (Amir, Foa, & Cashman, 1997; Riggs, Dancu, Gershuny, Greenberg, & Foa, 1992).

Thus, a number of factors must be taken into account in evaluating a trauma victim, including the nature of the trauma, the victim's prior psychological adjustment and trauma history, and the level of distress in the aftermath of the trauma. As will be discussed further in the sections on theory, the meaning of the trauma and changes in beliefs about the self and world are also important factors to consider.

6.22.4 THEORIES ABOUT PTSD

For over 100 years, reactions to trauma have captured the interest of theorists of psychopathology. Janet (1889) was among the first to develop an integrated theory about trauma, suggesting extreme stressors beseige the individual with an excess of thoughts and feelings too numerous or intense to integrate. Consequently, some individuals selectively attend away from the trauma, focusing instead on trauma-irrelevant thoughts and feelings. In this way certain trauma-related ideas become split off (dissociated) from consciousness, where they cause fragmented reliving of the trauma in the form of visual images, somatic states, emotional disturbances, or behavioral re-enactment. As will be evident in the discussion below, Janet's ideas about reactions to trauma have influenced both early and contemporary theorists.

6.22.4.1 Psychodynamic Theories

Freud's thoughts about the effects of trauma on the psyche have shifted over time (van der Kolk, Weisaeth, & van der Hart, 1996). In his early writing Freud was highly influenced by Janet, elaborating the dissociation phenomenon (Breuer & Freud, 1955). He later abandoned the dissociation theory, proposing instead that trauma reactions persist because of an association between the traumatic event and childhood repressed conflicts (Freud, 1953), thus rejecting the possibility that a traumatic event alone can cause severe emotional impact. Confronted by the grim effects on people of World War I, Freud focused again on external reality and returned to the view that the emotional upheaval generated by trauma is the source of traumatic neurosis. He suggested that the intensity of the trauma, the inability to find conscious expressions for it, and the unpreparedness of the individual cause a breach to the stimulus barrier and overwhelm the defense mechanisms (Freud, 1955).

6.22.4.2 Cognitive-behavioral Theories

Current cognitive-behavioral theory about the development and maintenance of PTSD stems from two lines of thinking. First is learning theory, which includes both classical and operant conditioning principles. Second is cognitive or schema theories, which propose evaluative processes as mediators in the development and maintenance of pathological anxiety. We will discuss how post-trauma psychopathology is conceived of within these two theoretical approaches and then present a third approach, emotional processing theory, that incorporates elements of the two within an information processing framework.

6.22.4.2.1 Learning theory

Mowrer's two-factor theory (1960) has been the most influential in the explanation of the pathological anxiety seen in PTSD. In this theory, fear is acquired through classical conditioning, in which a neutral stimulus (CS) is paired with an aversive stimulus (UCS), so that the CS comes to elicit a conditioned fear response (CR). Several theorists invoked this theory to explain the symptoms of PTSD (e.g., Foa, Steketee, & Rothbaum, 1989; Keane, Fairbank, Caddell, Zimering, & Bender, 1985; Kilpatrick et al., 1985), such that previously neutral stimuli that were present during the trauma come to elicit anxiety themselves. Through generalization and second-order conditioning, additional stimuli that are associated with either the feared stimuli or neutral stimuli that were present during the trauma also come to evoke fear. For example, words, thoughts, and images acquire the capacity to cause anxiety.

Subsequently, avoidance behavior is established through the process of operant conditioning. In this process, an individual learns to reduce trauma-related anxiety though avoidance of, or escape from, the CS. Escape and avoidance behaviors become established through the process of negative reinforcement, via their predicted capacity to end the aversive fear state. Because avoidance obstructs the realization that the CS has ceased to be followed by the UCS, fear is maintained.

6.22.4.2.2 Cognitive theories

Even during the influence of Mowrer's theory, discontent with non mediational accounts of anxiety stimulated the development of cognitive approaches. However, the originators of cognitive theory for anxiety disorders gave little attention to PTSD itself. They did suggest, though, that people with traumatic neuroses do not discriminate between safe and unsafe signals, and that their "thinking is dominated by the concept of danger." They also proposed that traumatic fear can be maintained through a sense of incompetence to handle stressful events (Beck, Emery, & Greenberg, 1985).

More specific hypotheses about cognitive factors that mediate emotional responses to trauma were advanced by scholars who employed personality and social psychology theories (e.g., Epstein, 1991; Janoff-Bulman, 1992; McCann & Pearlman, 1990). Central to their theories is the concept of schemas: core assumptions and beliefs that guide the perception and interpretation of incoming information. These theories share the supposition that processing a traumatic experience requires modification of existing assumptions. Based on Piaget's (1971) model of cognitive development, it is thought that such modification is accomplished through two mechanisms: assimilation and accommodation.

Both Epstein (1991) and Janoff-Bulman (1992) hold the position that people in general assume that the world is benevolent, the world is meaningful, the self is worthy, and that these assumptions are incompatible with a traumatic experience. Therefore, the victim must struggle either to assimilate the traumatic experience into the old set of assumptions or, more often, to change the assumptions such that they can accommodate the traumatic experience. Expanding on this view, McCann and Pearlman (1990) proposed seven fundamental psychological need areas: frame of reference, safety, dependency/trust of self and others, power, esteem, intimacy, and independence. Trauma, they argue, may cause disruptions in any of these need areas and thereby lead to troublesome emotions and thoughts or images.

Drawing on both psychoanalytic and information processing concepts, Horowitz (1986) suggested that individuals have a basic need to match trauma-related information with their "inner models based on old information" (p. 92). Recovery from trauma is a process of repetitive "revision of both [sources of information] until they agree" (p. 92), called the completion tendency, which is reflected in the re-experiencing symptoms observed in individuals with PTSD.

6.22.4.2.3 Emotional processing theory

Foa and her colleagues (Foa & Jaycox, in press; Foa & Riggs, 1993; Foa et al., 1989; Foa, Zinbarg, & Rothbaum, 1992) advanced a theory of PTSD that integrates learning, cognitive, and personality theories within an information processing framework, to explain why some individuals recover from a traumatic experience while others develop chronic disturbances. The starting point is the observation that emotional experiences are often relived well after the original emotional events have occurred, although the frequency and the intensity of emotional reliving usually decreases over time (Foa & Kozak, 1991). When these natural recovery processes are impeded, psychopathology emerges. To explain this pathological anxiety, Foa and Kozak (1985, 1986) adopted Lang's (1979) conceptual framework in which fear is viewed as a cognitive structure that serves as a program for escaping danger. Accordingly, fear is represented as a cognitive structure that includes three kinds of information: information about the feared stimulus; information about verbal, physiological, and overt behavioral responses; and interpretive information about the meaning of the stimulus and response elements of the structure. A fear structure is distinguished by the information that stimuli and/or responses are dangerous. In a subsequent exposition of emotional processing theory, Foa and Kozak, (1991) took the position that it is essentially this meaning information that distinguishes the fear structure from other information structures. With regard to PTSD, Foa and her colleagues (Foa & Jaycox, in press; Foa & Riggs, 1993) suggested that two classes of pathological cognitions underlie this disorder are: the world is utterly dangerous and the self is completely incompetent; a corollary of these is the idea that persistent PTSD symptoms are dangerous and are indicators of self-incompetence.

6.22.5 EFFICACY OF PSYCHOSOCIAL TREATMENTS FOR PTSD

Several types of psychosocial treatment have been employed for post-trauma disturbances, including hypnotherapy, psychodynamic psychotherapy, and cognitive-behavioral therapies. However, most outcome studies have focused on examining the efficacy of the latter (see Foa & Meadows, 1997, for a critical review). This section will review these studies.

6.22.5.1 Hypnotherapy

Hypnosis has long been used in the treatment of post-trauma disturbances (Spiegel, 1989). Freud used hypnosis to facilitate abreaction and catharsis, which he felt were necessary for recovery. Spiegel advocates the use of hypnosis in treating PTSD because processes akin to hypnotic trance, such as dissociation, occur naturally and are commonly used during or after a trauma. Spiegel proposes that hypnosis may facilitate the remembering of traumatic experiences that were encoded in a dissociative state.

Several case reports have described the usefulness of hypnosis for individuals with PTSD stemming from a variety of traumas (e.g., Jiranek, 1993; Kingsbury, 1988; Leung, 1994; MacHovec, 1983; Peebles, 1989; Spiegel, 1988, 1989). However, most of these lack methodological rigor and therefore the conclusions that can be drawn from them about the efficacy of hypnosis are limited.

One large controlled study compared hypnosis, desensitization, and psychodynamic psychotherapy with a wait-list control group among individuals who had experienced stressors (Brom, Kleber, & Defres, 1989). The majority of the participants, however, did not directly experience the traumatic event, but rather had lost a loved one. All three conditions produced superior improvement to the wait-list condition on self-report measures, but no differences across the three treatments were observed. Specifically, improvement in post-trauma symptoms was 29% for psychodynamic therapy, 34% for hypnotherapy, and 41% for desensitization, compared with about 10% improvement in the wait-list condition. This study offers evidence for the efficacy of hypnosis and other psychosocial therapies in reducing bereavement-related symptoms.

6.22.5.2 Psychodynamic Treatments

A variety of psychodynamic concepts have been utilized in individual and group therapy for trauma survivors (e.g., Horowitz, 1976; Yalom, 1995). For example, Horowitz's brief dynamic therapy emphasizes the concepts of denial, abreaction, catharsis, and stages of recovery from trauma in the treatment for post-trauma difficulties. The target of this brief psychodynamic therapy is the resolution of the intrapsychic conflict arising from the traumatic experience.

Only a few studies have been conducted to evaluate psychodynamic interventions for PTSD, and many have methodological difficulties that make their results difficult to interpret. One study used brief psychodynamic therapy to address difficulties following the Beverly Hills Supper Club fire (Lindy, Green, Grace, & Titchener, 1983). In this study, survivors included those present at the scene, rescue workers, people who lost significant others, and individuals who identified the bodies. Only 9 of 30 met criteria for PTSD prior to treatment. Survivors who agreed to be in the research study but did not request psychotherapy served as the comparison group. Patients who completed treatment exhibited somewhat lower symptoms than did patients who did not complete treatment and the non-treated comparison group did not improve as much as treatment completers.

Another study examined the efficacy of a group therapy based on Horowitz's (1976) model of responses to trauma with 13 sexual assault victims (Roth, Dye, & Lebowitz, 1988). The control group comprised 13 women who agreed to undergo assessements, and random assignment was not used. There were no clear effects at post-treatment, but high attrition rates in both the treated and control groups may have obscured effects. Results over a longer time period showed greater improvement in the therapy. Again, methodological problems render these results inconclusive. As described above, a study comparing Horowitz's (1976) brief psychodynamic therapy did as well as hypnosis, and desensitization; all did better than the wait-list control group (Brom et al., 1989).

In a study of psychodynamic treatment for conjugal bereavement, Marmar, Horowitz, Weiss, Wilner, & Kaltreider (1988) randomized bereaved individuals (widows) to 12 weekly sessions of either brief dynamic therapy or mutual help group treatment. Although death of a husband does not necessarily qualify as a *DSM-IV* trauma, some of the women in this study were diagnosed as having PTSD. Results indicated that patients in both conditions improved slightly, but there were no differences between groups. On one of many measures (the total score of the Symptom checklist, SCL-90) the dynamic therapy conditions showed greater reduction in symptoms at follow-up.

Scarvalone, Cloitre, & Difede (1995) used a quasi-experimental design to compare interpersonal process group therapy (IPGT) with a naturally occurring wait-list control in a sample of female childhood sexual abuse survivors, many of whom were diagnosed with PTSD. Patients in the IPGT group improved on a number of measures and fewer evidenced PTSD at post-treatment than in the wait-list group. However, because the evaluators were not blind to treatment condition, the extent to which expectancy for improvement influenced the evaluation is unknown.

6.22.5.3 Cognitive-behavioral Therapy

As noted earlier, cognitive-behavioral treatments have been evaluated far more extensively than have other psychosocial treatments for PTSD, via case reports and well-controlled studies. In this section, we will focus on controlled studies only that evaluate the efficacy of cognitive-behavioral programs developed to ameliorate PTSD symptoms: exposure therapy, anxiety management training, cognitive therapy, and their combinations.

6.22.5.4 Studies of Imaginal and *In Vivo* Exposure

Exposure therapy is a set of procedures that involve confrontation with feared stimuli, either *in vivo* or in imagination (e.g., flooding, systematic desensitization), which will be described in detail in the next section. With PTSD, exposure therapy typically includes repeated reliving of the traumatic event (in imagination) and *in vivo* confrontation with trauma-related situations that evoke fear but are not realistically dangerous.

Three controlled studies of male Vietnam veterans, each examining 6–16 sessions of imaginal exposure to the traumatic experience, have been conducted. In one study, patients were given up to nine sessions of imaginal flooding exposure in addition to "standard" treatment, or standard treatment alone (weekly individual and group therapies) (Cooper & Clum, 1989). In the second study, imaginal exposure (45 minutes of exposure preceded by relaxation) was compared with a no-treatment wait-list condition (Keane, Fairbank, Caddell, & Zimering, 1989). In the third study, all patients received group treatment. In addition to group treatment, half the patients received weekly imaginal exposure and the other half received weekly individual traditional psychotherapy (Boudewyns & Hyer, 1990; Boudewyns, Hyer, Woods, Harrison, & McCranie, 1990).

These three studies found that imaginal exposure produced some improvement in PTSD compared with the control groups, but the effects were rather small. In the Cooper and Clum (1989) study, imaginal exposure improved the PTSD symptoms, but had little effect on depression or trait anxiety. In the Keane et al. (1989) study a mixed picture emerged: therapists rated patients who received exposure as more improved on PTSD symptoms than control subjects, but on self-report measures of PTSD symptoms, no group differences emerged. However, patients who received exposure did rate themselves as more improved on general psychopathology measures than did those in the wait-list control. Boudewyns and Hyer (1990) found no group differences on psychophysiological measures, but the exposure group had improved more than controls on the Veterans Adjustment Scale at the three month follow-up.

Two completed studies of female assault victims examined the efficacy of exposure treatments for PTSD in comparison to other treatments and to wait-list controls. The assaults targeted for treatment occurred in all cases at least three months prior to treatment, to control for the effect of natural decline in symptoms that occurs shortly following an assault (Rothbaum et al., 1992). Exposure treatment consisted of nine twice-weekly individual sessions, seven of which included active exposure exercises and two of which were devoted to information gathering and education.

In the first study (Foa, Rothbaum, Riggs, & Murdock, 1991), exposure treatment (PE) was compared with stress inoculation training (SIT, which will be described later), to supportive counseling (SC), and to a wait-list control. Immediately post-treatment, patients in the PE and the SIT groups improved on all three clusters of PTSD symptoms. Patients in the SC and wait-list conditions evidenced improvement on arousal symptoms, but not on avoidance or re-experiencing symptoms. A follow-up evaluation that was conducted approximately three months after treatment revealed no differences between the active treatments; however, on all measures of psychopathology the PE group had less pathology. At follow-up, 55% of those receiving PE, 55% of patients who received SIT, and 45% of those receiving SC did not meet criteria for PTSD.

The second study compared PE, SIT, and a group treated with the combination of SIT and PE with one another and with a wait-list control group. All three active treatments showed significant improvement in PTSD symptoms, state anxiety, and depressive symptoms at post-test, and the wait-list did not improve. These treatment effects were maintained at the 3, 6, and 12 month follow-ups. On an index of good end-state functioning (defined as 50% improvement in PTSD symptoms, Beck Depression Inventory less than 9, and State-Trait Anxiety Inventory less than 40), 50% of patients who received PE achieved this criterion, whereas 37% and 38% of patients who received SIT and SIT/PE achieved the criterion, respectively; none of the patients in the control group reached this status (Foa, Dancu, Hembree, Jaycox, & Meadows, 1997). Moreover, those that received PE (PE or SIT/PE) improved more on all symptoms measures as compared with to those who did not receive PE (SIT or wait-list).

Two additional studies with female assault victims are in progress. Resick and colleagues (Resick, Nishith, & Astin, 1996) are examining the relative efficacy of PE and cognitive processing therapy (CPT), a therapy that will be described later when we discuss combined treatments. At post-treatment and at follow-up, both interventions resulted in large reduction of PTSD symptoms, but no clear group differences have emerged from the preliminary data. The second ongoing study (Foa, Jaycox, Meadows, Hembree, & Dancu, 1996) compares 9–12 sessions of PE alone with a program that includes PE and cognitive restructuring. Again, preliminary analysis suggests that both programs were highly effective but, unexpectedly, PE alone appears slightly more effective than the combined treatment.

One study that utilized a cross-over design examined the efficacy of PE with victims of diverse traumas, comparing the efficacy of *in vivo* and imaginal exposure by randomly assigning 14 patients with PTSD to one of two conditions: four sessions of *in vivo* exposure followed by four sessions of imaginal exposure; or eight sessions in the reverse order (Richards, Lovell, & Marks, 1994). Considerable improvement was observed in both groups, with symptom reduction between 65% and 80% and all patients losing the diagnosis of PTSD at post-test and at one-year follow-up. Results indicated that phobic avoidance was more reduced by *in vivo* than by imaginal exposure, regardless of the order in which it was received.

6.22.5.4.1 Studies of eye movement desensitization and reprocessing

A recently developed exposure technique called "eye movement desensitization and reprocessing" (EMDR; Shapiro, 1995), which combines imaginal exposure with saccadic eye movements, is beginning to be examined in empirical studies. However, to date, many of the outcome studies conducted have been plagued with methodological problems, making them difficult to interpret.

Several studies have compared EMDR to standard treatments in veterans, but none used independent evaluations of symptoms (e.g., Boudewyns, Stwertka, Hyer, Albrecht, & Sperr, 1993; Jensen, 1994). Another study that utilized a mixed sample of traumatized individuals, only some of whom had PTSD, showed that victims who received EMDR reported decreases in presenting complaints and in anxiety at post-test, whereas the wait-list group reported no such changes (Wilson, Becker, & Tinker, 1995). In an attempt to evaluate the effect of the saccadic eye movements, Pitman et al. (1996) compared EMDR to eyes-fixed exposure in a cross-over design using male veterans. No differences were found between EMDR and the eyes-fixed exposure condition on self-reported distress within sessions, with both groups showing modest gains on self-reported symptoms. Because these studies all relied solely on self-report data, the results may reflect expectancies for improvement after treatment rather than specific effects of EMDR.

Two studies did use independent evaluations of PTSD symptoms. The first used victims of heterogeneous traumas to compare EMDR with imagery habituation training and with applied muscle relaxation training (Vaughan et al., 1994). All three groups improved equally on independent ratings of PTSD symptoms after treatment. The second controlled study utilized female assault victims who had PTSD, and found EMDR to be more effective compared with a wait-list control group (Rothbaum, 1995). After four weekly sessions of EMDR, assessor's ratings of PTSD indicated 57% symptom reduction, and a self-report measure indicated 74% symptom reduction, and these gains were maintained at a three month follow-up.

In summary, the two controlled studies that used blind assessment provide preliminary evidence that EMDR is effective in the treatment of PTSD, but its value over and above other more established treatments is as yet unknown. Further studies about the efficacy of EMDR are clearly needed.

6.22.5.4.2 Studies of cognitive therapy and anxiety management training

Cognitive techniques aim at teaching patients systematically to examine and challenge maladaptive cognitions which are thought to underlie negative emotions. Early work with rape victims used cognitive therapy to address post-rape anxiety and depression, but these studies did not evaluate PTSD symptoms *per se* (Frank et al., 1988; Frank & Stewart, 1984; Turner & Frank, 1981). The therapy produced positive change on ratings of fear, anxiety, depression, and social adjustment. However, some patients had been recently raped, and therefore their improvement could reflect natural recovery. Although the effects of cognitive therapy on PTSD has not yet been studied, this therapy is often included as a component of anxiety management programs.

Anxiety management training (AMT) provides patients with a repertoire of strategies to handle anxiety. These include relaxation training (Bernstein & Borkovec, 1973; Jacobson, 1938), self-instruction (Meichenbaum, 1974), breathing retraining (Clark, Salkovskis, & Chakley, 1985), biofeedback (e.g., Blanchard & Abel, 1976), social skills training (e.g., Becker, Heimberg, & Bellack, 1987), and distraction techniques (Wolpe, 1973). AMT does not target specific mechanisms presumed to underlie anxiety, as exposure and cognitive therapy do, but instead aims to provide the patient with ways to manage anxiety when it occurs (Suinn, 1974). Because of the multiple elements contained in most AMT programs, it is not possible to determine the contribution of any specific procedure to overall outcome.

SIT (Kilpatrick, Veronen, & Resick, 1982) was developed as a treatment for rape victims with chronic disturbances. Modifying Meichenbaum's (1974) stress inoculation training, it included deep muscle relaxation training, breathing control, role playing, covert modeling, thought-stopping, and guided self-dialogue. In a sample of rape victims, Resick, Jordan, Girelli, Hutter, & Marhoefer-Dvorak (1988) compared the efficacy of a modified SIT, assertion training, and supportive psychotherapy with a naturally occurring wait-list control group. All three treatments were equally but only moderately effective in reducing trauma-related symptoms, depression, self-esteem, and social fears; gains were maintained at six month follow-up on rape-related fear measures but not on other measures. No improvements were found in the wait-list control group.

Two studies, described in Section 6.22.5.4, examined the efficacy of SIT with female rape and nonsexual assault victims who met criteria for PTSD (Foa et al., 1997, 1991). The SIT program in both studies was adapted from the Kilpatrick et al.'s (1982) program described above. In the first study, both SIT and PE produced significantly more improvement on PTSD symptoms than the wait-list group and supportive counseling immediately following treatment. However, patients who received PE continued to improve after treatment termination, whereas patients in the SIT and supportive counseling conditions evidenced no change between post-treatment and follow-up (Foa et al., 1991). In the second study, SIT, PE, and the combination both showed immediate and long-term (up to one year) treatment effects as compared with the wait-list. However, when patients who received SIT were compared with patients who did not, no significant differences emerged on any of the measures. Also the effect size for PE relative to the control condition was larger than that for SIT on all measures (Foa et al., 1997).

6.22.5.4.3 Studies of combination therapies

The success of both PE and SIT for rape-related symptoms spurred the development of combination programs that include confrontations with feared stimuli in combination with cognitive therapy or anxiety management skills. Two such programs have been studied with female assault victims who manifested chronic PTSD and a third one is currently being evaluated. The first consisted of the combination of SIT and PE (SIT/PE), already described above (Foa et al., 1997). Contrary to the expectations that SIT/PE would enhance treatment benefit, all three active treatments (SIT, PE, and SIT/PE) were effective in reducing PTSD severity. In fact, it appeared that PE was superior to SIT and their combination (Foa et al., 1997). Foa et al. suggested that since the combined treatment was delivered in the same number of sessions, it is possible that patients did not receive as much imaginal exposure as the PE group. Also, the SIT program contained seven different techniques, some of which may not be effective. As noted above, Foa and her colleagues are currently examining the relative efficacy of PE combined with cognitive restructuring to PE alone and to a wait-list control group (see Jaycox, Zoellner, & Foa, 1997, for a case example and discussion).

The second combined program for rape victims with PTSD is CPT and which has been tested in a quasi-experimental design (Resick & Schnicke, 1992). CPT can be conducted in a group format. It includes education, an exposure component consisting of writing the trauma narratives and sharing it with the therapist and group members, and cognitive restructuring. The efficacy of CPT was compared with that of a naturally occurring wait-list, but no random assignment was instituted. Patients who received CPT showed significant and lasting improvement whereas those on the wait-list did not. As noted earlier in the section on exposure therapy, Resick (Resick et al., 1996) is conducting a study comparing CPT delivered individually with PE alone. Preliminary results suggest that both programs are highly effective and do not differ from one another.

6.22.6 PREVENTION PROGRAMS

Many trauma researchers and mental health professionals emphasize the need for intervention immediately after a trauma, with the aim of preventing chronic disturbances (e.g., Bell, 1995). While there is scant evidence in support of the efficacy of immediate intervention, many programs have followed the "critical incident debriefing" model developed by Mitchell and Bray (1990). This program typically includes seven phases conducted in small groups and delivered within three days of the traumatic event: establishing the purpose of the debriefing and the ground rules, "recreating" the event by having all participants give their perspective on what occurred, discussion of individuals' thoughts during the event, description of the worst part of the event for each individual, discussion of reactions to the event, a presentation of common reactions to trauma by group leaders to normalize participants' responses, and a wrap-up phase.

These types of interventions have been applied to survivors of a variety of traumatic situations, including bank employees held at gunpoint (Manton & Talbot, 1990), emergency workers (e.g., Armstrong, O'Callahan, & Marmar 1991), and military personnel (e.g., Fitzgerald et al., 1993). However, the efficacy of these programs has not been ascertained in well-controlled studies and some uncontrolled trials suggest that the debriefing can have a deleterious effect. As noted by Raphael, Meldrum, and McFarlane (1995), randomized well-controlled studies of such programs have not yet been conducted.

The recognition that victims who exhibit severe reactions shortly after the trauma are more likely to develop chronic dysfunction (Riggs et al., 1995; Rothbaum et al., 1992) has prompted researchers to implement interventions that aim to prevent chronic PTSD. Foa and colleagues conducted a study to compare PTSD severity of 10 female assault victims who received a brief prevention (BP) program (four individual therapy sessions) with that of 10 matched victims who underwent an assessment procedure (Foa, Hearst-Ikeda, & Perry, 1995). Victims who received the brief prevention program showed symptom reductions of 74%, compared with a mean reduction of 33% in the assessment control group. Although the small sample size and lack of random assignment precludes drawing definitive conclusions as to the efficacy of the BP, the results are encouraging, and Foa and her colleagues are now studying this intervention in a larger sample of female trauma victims.

In summary, there is no evidence to date that the commonly used crisis interventions are effective, but they have not yet been rigorously tested. With female assault victims, short-term behavioral interventions may help in preventing chronic post-trauma problems. Foa and Meadows (1997) noted that one difference between the crisis intervention programs and the Foa, Hearst-Ikeda, and Perry (1995) study is the time frame in which the intervention was delivered. A typical crisis intervention is employed within three to four days after the traumatic event, whereas the BP program was instituted about two weeks post-trauma. Clinical observations suggest that during the first few days after the trauma victims are still disoriented and preoccupied with immediate logistical concerns, such as interaction with law enforcement or medical systems. Perhaps then a program that is implemented during this period cannot be processed adequately to provide benefit and may even add to the already existing state of confusion. Studies should investigate the optimal time for the delivery of crisis interventions.

6.22.7 PROLONGED EXPOSURE THERAPY FOR PTSD: THEORY AND PRACTICE

Despite a wide array of treatments that are being employed with trauma victims, most outcome studies focus on cognitive-behavioral programs which, as note above, were proven to be quite effective in ameliorating PTSD and related disturbances. Of these, exposure therapy seems to occupy a favored position. First, variants of exposure used with a variety of trauma populations, including veterans, assault victims, and sample victims of mixed traumas, have all indicated at least some degree of success. Second, the evidence for the efficacy of exposure comes from controlled studies conducted in different research centers, thus reducing the possibility of researchers' bias. In contrast, the two controlled studies on SIT were conducted in a single center, as were the studies of CPT. Third, PE has the advantage that compared with SIT and CPT, it is relatively straightforward and thus therapists can easily be trained to deliver it. Because of the apparent advantage of PE, we will focus on PE in the next section. We will first discuss the mechanisms thought to underlie exposure techniques as a background for understanding the subtleties of how to implement it successfully.

6.22.7.1 Mechanisms Underlying Prolonged Exposure

Emotional processing theory discussed earlier (Foa & Kozak, 1985, 1986) posits that, regardless of the type of therapeutic intervention, two conditions are required for fear reduction to occur. First, the fear structure must be activated via introduction of fear-relevant information, because if the fear structure is not activated (fear is not evoked), the structure would not be available for modification. In other words, successful treatment requires that the patient be engaged emotionally with the feared or traumatic material. Second, new information must be provided that includes aspects that are incompatible with the pathological elements, so that these can be corrected. Accordingly, successful therapy can be understood as correcting erroneous associations in the pathological fear structure targeted in treatment. In the case of PTSD, Foa and colleagues (Foa & Jaycox, in press; Foa & Riggs, 1993) suggested that treatment should correct the mistaken beliefs that "the world is extremely dangerous" and "I [the victim] am extremely incompetent."

As noted earlier, exposure procedures for PTSD consist of confronting the patient with trauma-related information, thus activating the trauma memory (i.e., eliciting the trauma-related fear). This activation constitutes an opportunity for corrective information to be integrated, and thus for the pathological elements of the trauma memory to be modified. Foa and Kozak (1986) suggested that fear reduction (habituation) within and across exposure sessions is an indicator that meaning changes in the fear structure have taken place. Several studies lend support to the proposition that emotional engagement or fear activation enhances treatment efficacy (c.f. Foa & Kozak; Kozak, Foa, & Steketee, 1988). Of particular relevance to PTSD are two studies demonstrating that emotional engagement with the trauma memory during treatment predicts successful outcome (Foa, Riggs, Massie, & Yarczower, 1995; Jaycox, Foa, & Morral, in press).

Several mechanisms have been proposed to underlie observed improvement of PTSD (Foa & Jaycox, in press; Foa & Riggs, 1993). First, repeated, prolonged, imaginal reliving of the trauma is thought to promote habituation of the anxiety previously associated with the trauma memory, thus correcting the erroneous belief common to patients with PTSD that anxiety stays forever unless avoidance or escape is realized. Second, deliberate confrontation with the feared memory blocks negative reinforcement, the process whereby relief of anxiety following cognitive avoidance of trauma-related thoughts and feelings reinforces avoidance behavior. Third, exposure to the trauma memory in a safe and supportive therapeutic setting incorporates safety information into the trauma memory, thereby refuting the belief that remembering the trauma is dangerous. Fourth, focusing on the trauma memory for a prolonged period helps the patient to discriminate between the trauma and other nontraumatic events, thereby rendering the trauma as a specific occurrence rather than a representation of a dangerous world and of an incompetent self. Fifth, successful reliving changes the belief that PTSD symptoms are a sign of personal incompetence to a belief that they are a sign of courage and competence. That is, the patient realizes that the distress experienced during reliving (PTSD symptoms) does not lead to anticipated loss of control or "going crazy."

Sixth, prolonged, repeated reliving of the traumatic event allows the patient to focus on specific elements of the trauma that drive negative evaluations about themselves, and to modify those evaluations. For example, a 25-year-old patient who suffered from PTSD following a rape by an acquaintance was convinced at the beginning of treatment that she was weak because she had not been able to prevent the rape. Through the process of imaginal reliving, she spontaneously realized "He was a very big man, and I am small," and this realization helped to modify her negative self-image.

In addition to the six mechanisms suggested above, Foa and Riggs (1993) suggested that the fear structures of traumatic memories are more disorganized than nontraumatic memories. A disorganized memory, they proposed, is particularly resistant to modification. Repeated, prolonged trauma reliving generates a more organized memory record that can be more readily integrated with existing schemas. Support for this contention comes from a study analyzing the victims' narratives of the trauma during exposure (Foa, Molnar, & Cashman 1995). Indices of disorganization, such as unfinished thoughts and repetitions, decreased from the first to the last narrative and this decrease was correlated with improvement.

Most of the mechanisms discussed above are also thought to operate in *in vivo* exposure. However, the most salient mechanism during *in vivo* exposure is the correction of overestimates of the probability of danger. As will be described in the next section, the trauma victim with PTSD often comes to fear a certain time of day, a physical characteristic of an assailant, or a part of the city because the fear has generalized to situations that bear similarity to the original trauma even when he or she is objectively safe. Some situations are avoided because they are reminders of the trauma and thus elicit distress and PTSD symptoms. Repeated confrontation with such objectively harmless situations is thought to prompt a more realistic appraisal of danger.

6.22.7.2 How To Implement Exposure-based Therapy

Often, cognitive-behavioral therapy (CBT) researchers neglect to discuss the therapeutic relationship when reporting outcome data. However, in CBT, just as in any other therapeutic environment, the therapist-patient alliance is indispensable. This is usually established in the first two sessions when the therapist elicits information about the trauma and its aftermath. This discussion provides an opportunity to express empathy and personal concern with the well-being of the patient. The therapy is presented as a collaborative effort, where the therapist and patient work together to achieve specific goals. With trauma victims, the explicit goal is the reduction of PTSD symptoms. Often patients are preoccupied with a number of other life issues, such as relationship problems, work stress, or parenting issues. These issues, while important, can divert attention away from the work on trauma-related disturbances and hinder treatment efficacy. Therefore, the therapist and the patient should come to an understanding from the outset that such issues will be set aside to be addressed after the exposure therapy has successfully been implemented. If daily crises around such issues are too pressing, the therapist and the patient may decide to delay exposure therapy.

6.22.7.2.1 Information gathering

Therapy begins with a comprehensive evaluation of PTSD and related symptoms, as well as information about the trauma itself. Objective characteristics of the trauma (e.g., extent of injury, time of day, characteristics of assailant) are important for treatment planning, so that the therapist can plan exposures that effectively address trauma reminders. Subjective factors of the assault (e.g., fear of death, dissociation during the trauma) are also important, since they will help guide the therapist to include these details in the imaginal reliving. A detailed trauma history will help the therapist identify the trauma or traumas that generate PTSD symptoms and make it the focus of treatment. In some cases, it is possible to work on more than one traumatic event sequentially during the course of treatment, especially if the traumas are similar.

6.22.7.2.2 Breathing retraining

Since exposure techniques involve direct confrontation with feared stimuli, PTSD symptoms often increase in the beginning of therapy and this should be discussed with the patient before exposure sessions begin. Training patients to use a simple relaxation technique helps ease this initial increase in distress. We have chosen breathing retraining in our program because of its versatility: patients can use this technique in almost any life situation without disruption of their activity or attracting the attention of others. Teaching this technique at the end of the first session seems to help the patient calm down after discussing in detail the traumatic experiences.

In breathing retraining the patient is taught to inhale a "normal" amount of air, and then to exhale very slowly (four or five seconds). During exhalation, the patient is asked to repeat the word "calm" or "relax" mentally and to hold his or her breath for about four seconds before inhaling again. Ideally, the therapist would practice this technique in the session, and to make an audiotape of the instructions and the demonstration for the patient's use at home. Patients are instructed to practice the breathing when they are relatively calm at first, and then begin implementing the technique when they are anxious.

6.22.7.2.3 Education about symptoms

Patients with PTSD interpret PTSD symptoms as a sign that they are "losing their minds," or "going crazy." It is extremely important to educate the patient about common reactions to trauma in order to provide them with a framework for understanding their own symptoms and to help them comprehend the treatment rationale. Education about reactions to trauma includes information about PTSD symptoms: the nature of fear and anxiety in response to triggers and cues, re-experiencing the trauma, concentration problems, feeling overly alert and on guard, avoidance of thoughts and feelings as well as reminders of the trauma, emotional numbing, and anger. In this context some related difficulties are discussed, including sadness about losses related to the trauma, feeling out of control or crazy, negative self-image and ideas of incompetence, lack of trust in others and thoughts about the whole world or all people being dangerous, relationship problems, sexual dysfunction or fears (usually following sexual assault), and a rekindling of emotion related to prior traumatic experiences. The education component is best delivered in an interactive, collaborative style, providing the patient with the opportunity to discuss his or her own symptoms and disturbing thoughts.

6.22.7.2.4 In vivo *exposure*

A crucial component of exposure therapy is its rationale. In exposure therapy the therapist is asking the patients to abandon their avoidance strategies used to manage their symptoms and instead to engage in imagery and in activities that are likely to cause some emotional distress in the beginning. Understanding the rationale for this therapy that "asks them to suffer" is essential for enlisting the patient's motivation. *In vivo* exposure aims at reducing the anxiety that patients with PTSD experience when they confront trauma reminders, and thereby return the patient to their pretrauma level of functioning. The rationale is explained as follows:

> In this program, we are going to focus on the fears that you are experiencing, and your difficulty coping, both of which are directly related to your assault. We've talked about the feelings, thoughts, and memories that are connected with the assault. We've also talked about some of the ways in which you are coping with that distress, such as avoiding situations and memories that remind you of the assault.
>
> Although most of the symptoms that you and I have talked about gradually decline with time after the trauma, for many victims like yourself, some of these symptoms endure and continue to cause marked distress. It is possible to spend up your recovery process by understanding what causes your reactions.
>
> A major factor is *avoidance* of situations, memories, thoughts, and feelings. It is quite normal for people to want to escape or avoid memories, situations, thoughts, and feelings that are painful and distressing. However, while the strategy of avoiding painful experiences works in the short-run, it actually prolongs the post-trauma reactions and prevents you from getting over your trauma-related difficulties. (The therapist may want to elicit examples of the client's avoidance based on previous discussion of common reactions.)
>
> When you *confront* the painful experiences, rather than avoid them, you will have the opportunity to process the traumatic experience. For example, if you avoid assault-related situations that are objectively safe, you do not give yourself the opportunity to get used to being in these situations. Unless you confront the situations, you may continue to believe that they are dangerous and that your anxiety in these situations will remain indefinitely. However, if you confront these situations you will find out that they are not actually dangerous and that your anxiety will diminish with repeated, prolonged confrontations. As a result of this process your symptoms will decline. The same is true for painful memories. For this reason we will ask you to relive repeatedly in your imagination the assault and to confront relatively safe situations that you are now avoiding.
>
> Today we are going to concentrate on your tendency to avoid situations and people that are related to the trauma. In order to help you stop avoiding situations and people that were once enjoyable or important to you, we are going to work together to make a list of situations that you have been avoiding since the assault. I call this list "the hierarchy." I also want to find out from you how much distress or discomfort these situations would cause you if you weren't avoiding them. Therefore I will teach you a method to indicate your level of distress. Of course we will not ask you to confront unsafe situations. The goal is not to help you view dangerous situations as safe, but rather to help you stop avoiding situations that are realistically quite safe. (Foa & Rothbaum, 1998)

After explaining the rationale, the therapist and patient construct a hierarchy of feared situations, listing all the situations or objects that the patient either avoids or endures with intense anxiety. The hierarchy may include situations that are directly related to the trauma (e.g., being in the place where the trauma occurred), or situations that have come to evoke anxiety through generalization (e.g., sleeping with lights off). A list of about 10 to 12 items is constructed and the therapist describes the "subjective units of distress" (SUDs) scale. The SUDs scale is anchored individually for each patient, so that a 0 indicates the most calm and relaxed that the patient has ever felt (e.g., lying on the beach); and a 100 indicates the most fearful or distressed the patient has ever been (e.g., during the trauma). The therapist then elicits SUDs ratings for each of the situations on the hierarchy, indicating the level of distress expected when confronting that situation. For example, Bonnie is a 37-year-old African-American woman who was raped by a male acquaintance in a friend's home. During the information gathering, she reported fear that had generalized to being alone in many public situations. Her *in vivo* exposure hierarchy follows:

50	sleeping with the door closed and curtains closed
50	taking the bus alone in the early evening
60	going to sister's house (near assault)
60	wearing a skirt on the bus in the early evening
75	sitting on a bench in a mall or shopping center
75	taking a walk alone (daytime)
75	walking by house where assault occurred with friend
100	sitting in park alone (daytime)
100	looking at pictures of assailant
100	sitting on steps of building where assault occurred with friend

After the hierarchy is constructed, specific instructions about how to implement exposure exercises between sessions are given:

> When you are practicing in the mall, for example, you may initially experience anxiety symptoms, such as your heart beating rapidly, your palms sweating, feeling faint; you may want to leave the situation immediately. But in order to get over the fear it is important that you remain in the situation until your anxiety decreases. Once your anxiety has decreased at least 50%, then you can stop the exposure and resume other activities. (Foa & Rothbaum, 1998)

In each session, *in vivo* homework assignments are reviewed to gauge progress and to make modifications if the patient has difficulty. Avoidance of homework is gently confronted and the rationale reviewed if necessary. New assignments are explicitly planned with the patient each session, and some discussion of logistical constraints, anticipated problems, and alternate plans are helpful. Of course, some *in vivo* exposure may also be conducted in session (e.g., looking at picture of the assailant) with the therapist's guidance.

6.22.7.2.5 *Imaginal exposure*

As described earlier, the first step in exposure treatment is explaining the rationale for the procedure. The following is an example of the rationale being explained to a patient:

> Today we are going to spend most of the session having you relive the memory of your assault in your imagination. It is not easy to understand and make sense of traumatic experiences. When you think about the rape, or you are reminded of it, you may experience extreme anxiety and other negative feelings such as shame or anger. The assault was a very frightening and distressing experience, so you tend to push away or avoid the painful memories. You may tell yourself, "Don't think about it; time heals all wounds" or, "I just have to forget about it." Other people often advise you to use these same tactics. Also, your friends, family, and partner may feel uncomfortable hearing about the assault, and this may influence you not to talk about it. But, as you have already discovered, no matter how hard you try to push away thoughts about the assault the experience comes back to haunt you through nightmares, flashbacks, phobias, and distressing thoughts and feelings. These symptoms signal us that your assault is still "unfinished business." In this treatment our goal is to help you process the memories connected with the assault by having you remember them for an extended period of time. Staying with these memories, rather than running away from them, will help decrease the anxiety and fear that are associated with them. It is quite natural to want to avoid painful experiences such as memories, feelings, and situations that remind you of the assault. However, as we already discussed, the more you avoid dealing with the memories, the more they disturb your life.
>
> What we are going to do today is to begin helping you process the memories associated with your assault. The goal of imaginal exposure as well as *in vivo* exposure is to enable you to have thoughts about the rape, talk about it, or see triggers associated with it without experiencing intense anxiety that disrupts your life. This part of the program includes having you confront situations and memories that generate both anxiety and an urge to avoid. Gradually, the memories will become less painful. You will get used to them.

> Remember, we call this "habituation." Before we begin, do you have any questions about anything that I have said?
>
> Repeated reliving of the trauma will also help you in other ways. It will teach you that remembering is not re-experiencing the trauma. In other words, it will help you discriminate between remembering the trauma and being traumatized again. There is no danger in remembering and therefore there is no good reason to become overwhelmed with anxiety every time that you think about the rape. Also repeated reliving will teach you that you are not going to lose control or go crazy if you engage with the traumatic memory. On the contrary, through repeated reliving of the rape you are going to gain control over your memories instead of them having control over you.
>
> And finally, engaging with the traumatic memory repeatedly will allow you to differentiate between the traumatic event and other events that are similar but not dangerous. For example, now you are afraid of all bald men because you were raped by a bald man. By repeated reliving of the rape you will realize that "baldness" itself is not dangerous. (Foa & Rothbaum, 1998)

After explaining the rationale, the therapist explains the method for prolonged imaginal exposure or reliving of the traumatic experience. The patient is asked to relive the trauma vividly by describing it in the present tense, with eyes closed. Patients are instructed to include in the trauma recounting details of the physical environment, their actions; others' actions; their thoughts and feelings; and bodily sensations that had occurred during the trauma. Because of the findings that emotional engagement enhances treatment efficacy, the therapist emphasizes the importance of reliving the emotions that were experienced at the time of the trauma. An example of the instructions is as follows:

> I'm going to ask you to recall the memories of the assault. It is best for you to close your eyes so you won't be distracted and so that you can envision these events in your mind's eye. I will ask you to recall these painful memories as vividly as possible. We call this "reliving." I don't want you to tell a story about the assault in the past tense. What I would like you to do is describe the assault in the present tense, as if it were happening now, right here. I'd like you to close your eyes and tell me what happened during the assault in as much detail as you remember.
>
> We will work on this together. If you start to feel too uncomfortable and want to run away or avoid it by leaving the image, I will help you to stay with it. We will audiotape the narrative so you can take the tape home and listen to it for homework. From time to time, while you are reliving the assault, I will ask you for your anxiety level on the 0 to 100 SUDS scale, in which 0 indicates no anxiety or discomfort and 100 indicates panic-level anxiety. Please answer quickly and don't leave the image. Do you have any questions before we start? The rating should indicate how anxious you are at the time I ask, sitting here in my office, not how you felt during the assault. (Foa & Rothbaum, 1998)

The therapist may probe for more information if the patient does not provide enough detail. The reliving exercise is maintained continuously for 45–60 minutes, without discussion or interruptions, and is tape-recorded. If recounting the entire trauma takes less than the allotted time, the therapist asks the patient to repeat it over again, until the full time is completed. Thus, several repetitions of the trauma may occur in each session. Ideally, reliving should continue until some reduction in anxiety takes place, but it is sometimes necessary to end the exercise without reduction in SUDs. In the first few sessions, reliving should focus on the entire trauma, but in successive sessions, the therapist and patient select the most distressing parts, as indicated by high SUDs levels, as the focus of the reliving. We call these parts "hot spots" and they usually represent the most distressing moments during the trauma. The entire session can be focused on one or two hot spots. Once these hot spots are being processed and habituation occurs, the distress during the remaining parts of the trauma narrative usually diminishes. We advise that towards the end of treatment the entire trauma be relived again so that any newly emerging hot spots can be addressed before therapy is completed.

The patient takes home the audiotape of the reliving exercise, and is instructed to listen to it daily while imagining the trauma as vividly as possible. At the end of each reliving session, the therapist and patient discuss changes in the reliving experience within and between sessions, and the therapist reinforces the patient's ability to confront such painful information without losing control or going crazy.

6.22.7.3 Indications and Contra-indications

As noted earlier, often in the beginning of exposure treatment, the patient experiences an increase in anxiety owing to the confrontation with trauma reminders. Because of this initial increase in anxiety, patients should be relatively stable prior to the beginning of therapy. Thus, active psychosis, alcohol or drug dependence, or self-injurious behavior should be addressed prior to implementing exposure therapy. In addition, there is some indication that exposure to an event about which the patient feels intense guilt or shame, rather than fear, is contraindicated, since imaginal exposure in such cases can accentuate guilt and shame (Pitman et al., 1991).

Other factors that require attention may not become apparent until exposure is initiated. These include severe anger, overwhelming anxiety, and emotional numbing (see Jaycox & Foa, 1996; Jaycox, Zoellner, & Foa, 1997).

6.22.7.3.1 Anger

Anger is a natural response to a traumatic event. Often there is an identifiable party that can be blamed for the trauma (e.g., the manufacturer of faulty equipment, the assailant), and anger towards these parties appears to be justified. Even when the blame cannot be clearly ascribed to another, as in some cases of natural disaster, trauma victims often experience a basic sense of injustice (e.g., "Why me?"). Not surprisingly, then, anger is one of the defining symptoms of PTSD.

While some anger is a frequent feature of the PTSD clinical picture, studies suggest that anger may have a role in the formation or maintenance of chronic post-trauma disturbances. For example, Riggs et al. (1992) found that female victims of a recent crime who reported higher anger within two weeks of the assault, also reported higher PTSD symptom scores one month later. The authors hypothesized that intense anger impedes the natural recovery process by interfering with activation of the fear associated with the trauma, thereby obstructing emotional processing.

During treatment, intense anger appears to impede improvement in therapy by hindering emotional engagement. Facial fear expressions during the first reliving of rape memory during therapy predicted improvement following exposure therapy and were inversely related to self-reported anger prior to treatment (Foa, Riggs, Massie, & Yarczower, 1995). Moreover, anger at pretreatment was negatively correlated with improvement. The latter result was replicated in a larger sample (Jaycox, Perry, Freshman, Stafford, & Foa, 1995).

In contrast to severe and constant anger, clinical observations suggest that moderate episodic anger and irritability do not seem to impede improvement in therapy. That is, a certain degree of increase in anger is expected as anxiety increases during the initial stage of therapy, and this anger usually dissipates as arousal decreases. Thus, the therapist is advised to contract with the patients to delay addressing anger-related issues until other emotions such as fear have been processed.

6.22.7.3.2 Emotional Numbing

Numbing of emotions, such as anger, is part of the definition of PTSD. Numbing is usually defined as including several symptoms that constitute part of the avoidance cluster in PTSD: disconnection or detachment from others, blunted emotional responsiveness or expression, and lack of enjoyment in activities (e.g. Foa & Riggs, 1993; Foa, Riggs, & Gershuny, 1995; Litz, 1993). Foa and Riggs noted that the inclusion of numbing with effortful avoidance symptoms reflects the view that these symptoms are motivated and maintained by their capacity to reduce distress. It follows that direct confrontation with feared stimuli will exacerbate numbing in patients who use it as a coping strategy. However, increased numbing would be expected to obstruct emotional processing since it would hinder fear activation, thereby decreasing the effect of treatment. One way to overcome the obstacle presented by numbing during the exposure exercise is to remind the patient of the rationale for reliving. The therapist is also advised to probe for details, thoughts, and feelings during the imaginal exposure.

6.22.7.3.3 Overwhelming anxiety

Although a rare occurence, patients may become so engaged in the reliving exercise that they experience the traumatic memory as if the trauma is actually reoccuring. Consequently, the patient experiences the same overwhelming anxiety and lack of control as he or she did during the trauma. This flashback usually happens when the patient fails to incorporate into the traumatic memory the information that he or she is in a safe place, that is, in the therapist's office. The therapist can take measures to remind the patient that he or she is remembering the trauma, not re-experiencing it. For example, the therapist can instruct the patient to relive the trauma with eyes open rather than closed, or can insert additional encouraging and reassuring comments during the procedure.

In summary, the therapist should be attentive to these obstacles to exposure therapy, and should modify procedures, when needed, to overcome them (Jaycox & Foa, 1996). In addition to modification of the exposure techniques, the therapist may wish to consider alternative techniques, such as relaxation training to address overwhelming anxiety, or cognitive restructuring to address anger and guilt. These techniques are clearly helpful for trauma victims, as reviewed earlier, and can therefore be used to augment or replace exposure techniques in difficult cases.

6.23.1 INTRODUCTION

The effective management of people with severe and enduring mental illness poses a number of complex psychological, social, and economic problems. It begins with the application of a range of therapeutic interventions—drugs, cognitive-behavioral therapy (CBT), "Expressed Emotion (EE) based" family therapy, etc.—all aimed at addressing treatable symptoms, but goes on to include "management" interventions aimed at helping the individual make a positive psychological adjustment to their difficulties and in facilitating their social reintegration. It is this dimension of managing chronic disability, with particular emphasis on the importance of social outcomes, which form the core of modern concepts of mental health rehabilitation and which mark out the care of severe and long-term mental illness from more straightforward, "treatment oriented" models. In this chapter we will focus specifically on the contribution of clinical psychology to this process.

Rehabilitation remains one of the most poorly understood areas of mental health. Traditionally, it has been synonymous with improving the functioning of long-stay patients in institutions so that they can move out of hospital and live independently in the community, but this is now no longer of much relevance. As the locus of care for most people with severe and enduring mental health problems has shifted from hospital to community, so our ideas about their long-term management has also changed to reflect a much more dynamic view of the interaction between the psychiatrically disabled person and his/her social environment. Rehabilitation has become much more than a set of techniques aimed at a single "end point": it is a "philosophy," a way of looking at the psychological and social problems of people with severe and long-term mental health difficulties in their social context. It also provides a framework in which the social/environmental dimension has as much place as the biological and in which the management of "chronic" disabilities is just as important as the treatment of symptoms. These ideas form the conceptual framework for this chapter.

But how can we provide operational definitions for "severe and long-term mental illness"? How can we produce a psychological formulation for the management of severe and long-term mental illness which links together biological, psychological, and social influences? What are the options in terms of delivering a service to people with these kinds of problems and can we be confident that they will meet their needs? What do we know about the effectiveness of different models of service delivery and what are the methodological limitations of this evidence? How can we go about effectively involving users in the planning and development of services and what implications does this have for staff and staff training? These are the specific questions we need to address. Let us begin with the question of definition.

6.23.2 DEFINING SEVERE AND ENDURING MENTAL ILLNESS

As community-based services for the care of people with severe and enduring mental illness have begun to develop, so it has become increasingly clear that we need to define the "severely mentally ill" in order to discriminate them from the majority of those using mainstream mental health services. These questions of definition have real practical significance as, without clear definitions, priorities cannot be set and scarce resources cannot be targeted to those in greatest need.

Attempts to define severe and persistent mental illness have generally relied on multidimensional criteria (Bachrach, 1988; Powell & Slade, 1996; Schinnar, Rothbard, Kanter, & Jung, 1990). These usually employ a combination of diagnosis (usually major psychosis); indices of service contact (frequency and duration of admissions); presence of disability (long-term difficulties with social functioning and adaptation); availability of formal and informal support; and degree of risk to self or others. The typical criteria used are set out in Table 1.

The criteria in Table 1 highlight the issue of "comorbidity" in defining "severe and enduring mental illness." It is not just that these individuals may be suffering from the active symptoms of major mental illness (schizophrenia, bipolar disorder), they also have a range of social and occupational problems (poor or unstable housing, poor work records, lack of social support) and may pose periodic risks to their own safety and/or those around them. It is this combination of problems and needs which makes this population particularly difficult to care for—and often particularly difficult to engage in conventional services. Thus, from a clinical psychology point of view, it may seem difficult to know where to "start." They have so many problems, and there are so many possibilities in terms of intervention, that the difficulty is in selecting the most potentially effective strategy (and, as we shall see later, this may not always be a strictly "psychological" intervention). Nevertheless, the skills of a clinical psychologist are highly relevant when it comes to assessing needs for care, formulating care packages, and delivering effective interventions.

Notwithstanding the difficulties, such a list of defining criteria also give those in a local service a useful basis for defining those patients in their locality who have the greatest needs for complex, long-term, management programs and who may therefore form the target for specialist community teams. These individuals are actually already likely to be known to a variety of local agencies (e.g., inpatient teams, primary health care, police, accident and emergency services, etc.) and it is often useful to begin by cross-checking the list of names with each of the agencies. A local "case register" can then be compiled which may be used for subsequent planning and monitoring of the service (for an example of this approach in action, see Audit Commission, 1994, p.55).

6.23.3 A PSYCHOLOGICAL FORMULATION

Having operationally defined severe and enduring mental illness we then need a psychological formulation which will help us organize our thinking and bring together information in a way that has both theoretical and practical implications for the management

Table 1 Criteria for defining people with severe and enduring mental illness.

A typical "severely mentally ill" person might be expected to have:
(i) diagnosis of schizophrenia or major affective psychosis
  and
(ii) at least two admissions in last year or six months continually in hospital in the last three years
  and
(iii) significant problems functioning in at least two of the following areas:
  basic literacy and numeracy
  self-care
  financial support (including money management).
  housing (poor quality or unstable).
  lack of social supports
  lack of occupation/employment
  difficulties with close personal relationships (family, etc.).

In addition, they are likely to show:
(i) poor compliance with prescribed medication
(ii) some degree of drug/alcohol abuse
(iii) difficulties in engaging in follow-up and aftercare
(iv) frequent crises and re-admissions
(v) significant history of self-harm, self-neglect, or harm to others

of care. The classic formulation, enshrined in the World Health Organization (WHO) classification of *impairment*, *disability,* and *handicap*, is derived from the pioneering work of the English social psychiatrist John Wing (Wing, 1978).

Impairment refers to disturbances in function at the level of organ or bodily system. For example, in schizophrenia brain functioning appears to be impaired in relation to neurotransmission in dopaminergic pathways and this gives rise to the primary symptoms such as hallucinations, thought disorder, etc. *Disability* refers to the effects of primary impairment on the person's ability to perform a range of necessary social tasks and roles, for example, to shop, to cook, to work, to keep oneself reasonably clean and tidy, to establish and maintain relationships, etc. A characteristic of disabilities is that they are long term and persist after symptoms have been treated and must therefore be regarded as semipermanent difficulties in functioning. Adverse personal reactions to illness (loss of confidence, denial, loss of motivation) are often also regarded as disabilities because their effects may be enduring. A person may thus be "disabled" by their illness without it necessarily having a direct or long-lasting effect on their cognitive or intellectual ability simply through its impact on their self-confidence and self-esteem. The importance of these adverse personal reactions and their implications for models of management will be addressed in more detail later. *Handicap* then refers to the *social* consequences of impairments and disabilities, for example, unstable housing, poor work record, loss of social supports, stigma, etc. Again, the degree of handicap may not be proportionate to either the degree of impairment or the level of disability. Thus, a person may be symptomatically quite well recovered, with little residual disability, but still very handicapped because of the reactions of those around him/her—friends, employers, neighbors, etc. Again, more will be said about the independence of symptoms, functioning, and social adjustment in the following paragraphs.

Although it is sometimes difficult to be sure in a given case how much a person's problems are related to the underlying impairment, how much is disability based on an adverse personal reaction, and how much is due to social handicaps, nevertheless this conceptualization provides a useful heuristic to help us think about the design and implementation of multifaceted interventions—biological, psychological, social—which will separately address these different areas of need.

The distinction between symptoms and functioning was first clearly demonstrated in the classic studies on the course and outcome of schizophrenia (Strauss & Carpenter, 1974, 1977; Strauss, Klorman, & Kokes, 1977). They showed that each outcome "domain"—symptoms, social functioning, work—was relatively independent of each other. This is analogous to the "desynchrony" observed between different outcomes in other kinds of mental health problems (e.g., fear and anxiety, see Rachman & Hodgson, 1974) and has important implications for both treatment and management. For example, it implies that changes in symptoms may not always produce generalized improvements in functioning. Thus, the person may show positive improvements in symptoms, while remaining socially quite disabled. Indeed, this is quite common (De Jong, Giel, Sloof, & Wiersma, 1986). Conversely, it may be possible for an individual to function quite well socially and vocationally while still experiencing severe symptoms. This is probably less common, but certainly not rare. Interventions therefore need to be targeted to producing specific changes in functioning and it cannot be assumed that if symptoms are treated (whether physically or psychologically) then this will automatically have a generalized effect on behavior.

By definition, "enduring mental illness" is long-term and a psychological model of rehabilitation therefore has one other cardinal feature: it is concerned with people who may not "get better." Rehabilitation asks, "How can we help people manage despite their disabilities?" It says, "By all means try and treat people, but if they don't respond then how can we help them make the best adaptation possible, given the fact that they have difficulties in functioning which are, in the current state of knowledge, essentially untreatable?"

This concept of psychological "disability" (i.e., untreatable symptomatology) still creates problems for many mental health professionals. They do not like to admit the existence of problems which they cannot do anything about and managing disabilities seems an altogether less glamorous—and lower status—activity than treatment and "cure." In dealing with people with severe and enduring problems, many professionals therefore find themselves in a state of psychological "dissonance," that is, there is a discrepancy between their expectations of themselves and what they find they can achieve with their patients. There is then a temptation to resolve this conflict either by devaluing the patient (i.e., "they are untreatable and therefore not worthy of further time and resources") or by feeling personally devalued ("I am ineffective and therefore don't have anything to offer this person"). Either way, staff may wish to avoid or withdraw from those with the most severe problems and seek out more therapeutically "promising" clients. This is compounded by a culture in which health services are very "outcome" and "throughput" oriented—often for simple, financial reasons. Long-term, intractable difficulties are therefore unwelcome news for both clinicians and managers alike and the challenge of rehabilitation services is how to think creatively about services which will promote social functioning and facilitate social reintegration while, at the same time, accepting the possibility of very small and slow changes over time. This can only be based on a sophisticated psychological understanding of the nature of the problems and the difficulties that they cause both for the patients and for the staff and other carers who are looking after them.

In stressing the importance of disability, we should also emphasize that psychiatric disabilities are not fixed and immutable in the same way as physical disabilities. In physical rehabilitation, the problems of adaptation may be solved by the provision of a range of physical supports (e.g., wheelchairs, ramps, large print, induction hearing loops, etc.). By contrast, the problems of the psychiatrically disabled person center around "social access" (e.g., to ordinary housing, ordinary jobs, nonsegregated leisure activities, etc.) and these depend on the provision of social supports—families, professionals, nonprofessional carers, etc.—and social attitudes (e.g., of friends, family, employers, etc.). Long-term social adaptation will be largely determined by the stability of these supports and, since they are very much dependent on individuals, they are inherently fragile. Social tolerances may also change: employment opportunities may diminish (or increase), people become tired, move on, get promoted, lose hope, die, etc. The pattern of psychiatric disabilities therefore can change—both for the better and the worse—and rehabilitation services have continually to monitor and adjust the level of their interventions, offering more, or less, support as the person's social circumstances change. Good rehabilitation is about the quality of this "continuing care" and how to achieve this through effective teamwork, training, and leadership are all topics to which we shall return to later.

This formulation of the dynamic nature of the relationship between the individual's functioning and the social environment lies at the heart of our current attempts to provide "community care." Psychiatrically disabled persons living in the community are struggling to maintain their social adaptation, while being constantly exposed to a changing (and therefore stressful) social environment. In these circumstances, it is not surprising that their adaptation breaks down from time to time and they need to be "rerehabilitated." This is not "failure": it is the inevitable outcome of change, life events, and limited coping capacities. But it does imply a very specific approach to the organization of services and to the training and support of staff and family carers.

How the organization of mental health services for people with severe and long-term mental health problems has changed over the last 40 years and what implications this has for the context in which professionals, patients, and their families now have to operate will now be discussed.

6.23.4 CHANGES IN THE ORGANIZATION OF MENTAL HEALTH SERVICES

Most countries have been struggling to move away from an organization of mental health services that depends heavily on residential provisions sited in large, old, psychiatric hospitals. This change is partly motivated by a belief—now supported by considerable evidence—that most people with serious and enduring mental health problems prefer to live and function better in various kinds of sheltered and supported settings in the community where they can have access to the same range of activities and social supports that are available to every other citizen.

The movement towards the community has proceeded at different rates in different countries. Some (e.g., The Netherlands) have managed to maintain a very good standard of care in their hospitals, while at the same time vigorously developing community alternatives. Others—and here the UK is a good example—have had more difficulty in ensuring adequate access to inpatient provision (both short- and long-term) as the overall number of long-stay beds has reduced. These changes have confirmed the warnings of scholars like Leona Bachrach who reminded us more than 20 years ago that the traditional mental hospital was a complex organization, fulfilling a number of medical, psychological, and social needs and that, if we had ambitions to manage without it, we would need to develop an equally complex range of services in the community (Bachrach, 1976).

All countries have experienced some difficulties in ensuring that there is an adequate range of housing, occupation, social, psychological, and medical support for all those who need it. Part of the reasons for this are clearly financial, but part are also related to the difficulties of interagency cooperation implied by such an agenda (Mechanic & Aiken, 1987). To recreate comprehensive community services for the most severely psychiatrically disabled demands a high level of cooperation between different providers—health, social services, housing agencies, work and occupational programs, primary care teams, etc. These agencies are all organized and managed differently, with different priorities, different planning cycles, and different funding streams. It is therefore not surprising that effective interagency cooperation is difficult to achieve and that there have been repeated calls for health and social care agencies to work more closely together. This has certainly been the thrust of successive planning guidance from the UK Department of Health (e.g., Department of Health, 1995). However, simply extolling the need for greater cooperation does not solve the bureaucratic and organizational problems of getting large agencies, with very different cultures, to understand one another's aims and priorities. These are essentially social and psychological problems and require psychological solutions.

The model of a single agency provider has actually been subject to experimental evaluation in the US through the Robert Wood Johnson Foundation program (Goldman, Morrisey, & Ridgely, 1994). This ambitious project aimed to create unified mental health authorities across eight US cities. In organizational terms it generally succeeded very well, however, it failed to deliver much in the way of improved health and social outcomes for patients, mainly because insufficient attention was paid to changing the practice of professionals through new training initiatives, staff development, and support (Lehman, Postrado, Roth, McNary, & Goldman, 1994; Morrisey et al., 1994). The lesson is clear: organizational change is not enough. If services are going to improve we therefore need to think about how to change the behavior of staff as well as how to change organizational structures.

However, in both the US and the UK there have been substantial reductions in long-stay beds in mental hospitals over the past 40–50 years (Bachrach, 1997). In the US there has been an 86% reduction in the number of beds provided in state hospitals over a period of 40 years (560 000 in 1955 to 77 000 in 1995). In the UK, there has been a similar dramatic reduction (from 155 000 in 1955 to less than 25 000 today). What effects have these changes had on the overall service "systems" and on the lives of individual patients and their families?

At the outset, it is important to distinguish between those "old" long-stay patients who have been most directly affected by the reductions in mental hospital beds and the next generation of potentially "new" long-term patients who would perhaps have gone into long-stay beds in the past, but for whom this is now no longer an option. Many of the "old" long-stay patients have simply swapped one form of institutional care for another (so-called "transinstitutionalization"). However, the quality of their lives may still have improved, providing the new accommodation is at least superior to a large, impersonal, and old-fashioned psychiatric hospital. But the "new" long-term patients: young, with major mental illness, severe symptoms, often complicated by drug and/or alcohol misuse, sometimes with a history of violence or self-harm, have fared less well. They may have ended up in acute inpatient units, often on general hospital sites, and become "new" long stay inpatients (Lelliot, Wing, & Clifford, 1994; Mann & Cree, 1976). Alternatively, they may be caught in the "revolving door" of acute admission, followed by premature discharge to inadequate support in the community, leading to rapid relapse, and re-admission. Most worrying of all, they may have dropped out of formal mental health services altogether and be existing on the margins of society, in poor or unstable housing, on the street, or in prison. They are the most obvious casualties of these changes in the patterns of service provision. Let us now examine the fate of these two groups in more detail.

As indicated, the quality of life for older patients who have been reprovided for in the community as part of a systematic reduction in beds in old, psychiatric institutions may or may not have been enhanced depending on the quality of their new accommodation. It is difficult to generalize because so much depends on local conditions, but the largest study of its kind in the UK (possibly in the world) of the outcomes for patients moved from two large psychiatric hospitals in North London—the so-called TAPS (Team for the Assessment of Psychiatric Services) study—suggested that those who move into reasonably good-quality residential care generally showed similar clinical and symptomatic outcomes compared with matched cohorts who remained in hospital, had better social outcomes, enhanced social networks, showed decreased behavioral problems and improved medication compliance, and were much happier with their living situation, compared with matched cohorts who remained in hospital (Leff, 1997). There was no evidence of increased death rates, suicide, crime, or vagrancy. The cost of care in the community was generally slightly less than of continuing care in hospital, but showed significant increases with increasing levels of disability (Beecham et al., 1997).

A more detailed study by Shepherd, Muijen, Dean, and Cooney (1996) attempted to examine some of the variability in the quality of care in residential provision for ex-long-stay patients in the community. They surveyed 20 residential homes in the London area, all of which had been established in connection with mental hospital closure programs. The homes were selected randomly to represent the range of current providers (housing associations, local Social Services departments, private-for-profit, etc.) and were compared with a small sample of "rehabilitation" wards from the local psychiatric hospitals. Residents and staff were assessed using a battery of standardized measures, the organization and quality of care was examined, and care was directly observed using a behavioral observation measure. Residents were also interviewed individually to determine their quality of life and satisfaction with their current living situation.

The results showed that the most disabled residents were concentrated in hospital, which generally offered the poorest quality of care and the most "institutionalised" staff. Not surprisingly, patients in hospital were much less satisfied and complained of lack of privacy, autonomy, and independence. In comparison with the large differences between hospital and community, the differences between community providers were small. Although, as in hospital, the personality and leadership style of the project manager appeared to be very important. Where project leaders encouraged a positive and respectful attitude towards residents, other aspects of the quality of care appeared to be good. Where they were more careless or neglectful, then this was also usually reflected in the overall running of the home. This study was consistent with the findings of the TAPS team in suggesting that for most of those directly affected by reductions in long-stay beds, the quality of their care has improved and, with it, their perceived quality of life. For them, community care has been a success and certainly has proved preferable to life in a traditional, psychiatric institution.

It is important to recognize that the reduction in hospital beds does not necessarily mean that there has been a reduction in the overall amount of residential provision. As the notion of transinstitutionalisation implies, the system of care may have changed in terms of who is providing residential accommodation, but the absolute number of places may not have altered greatly. This is illustrated by Martin Knapp and his colleagues, again in the TAPS study, who showed that there has been a significant growth in provision managed by "voluntary" and "independent sector" organizations. (These are a mixture of private "for profit" and "not-for-profit" providers). In the UK, this almost completely compensated for the loss of inpatient beds (Knapp, Beecham, & Hallam, 1997). However, the "mixed economy" of care does pose problems in terms of regulation and the monitoring of standards and it is worth remembering that the public mental hospital system was created precisely because of fears that a private system would be difficult to regulate and inspect (Jones, 1972). Such problems do not go away.

Probably the most important effect of the reduction in mental hospital beds in the UK has been the impact on the current acute services caused by the failure to develop adequate alternatives to long-stay inpatient provision.

This is illustrated in another recent study in the UK by Shepherd, Beardsmoore, Moore, Hardy, and Muijen (1997). They constructed a nationally representative sample of acute psychiatric units, stratified according to levels of local social deprivation. Information was then collected regarding the numbers of available beds, staffing levels, and "activity" (i.e., throughput). The range of local services, such as community mental health teams, crisis services, and supported housing was also described. A census was completed of all the patients resident on a given day and background data collected together with ratings of clinical and social functioning using the "Health of the Nation Outcome Scale" (Wing, Curtis, & Beevor, 1996). Staff were also asked to indicate whether or not they judged that the individual still required to remain on an acute inpatient ward and completed a standardized checklist covering the possible reasons preventing discharge or transfer to a more appropriate setting.

The results provided information on over 2000 patients admitted on nearly 40 sites covering approximately half the population of England and Wales. Fifty-two percent were female; the mean age was 41 (s.d. = 15.07), 88% were White; and 30% were currently detained under a Section of the Mental Health Act. Seventy-four percent had a diagnosis of schizophrenia or mood disorder. Diagnoses of substance abuse, neurosis, and personality disorder accounted for another 6% each. The median length of stay was 28.5 days, but 7% had current lengths of stay greater than six months (i.e., would be classified as "new" long stay). Their prevalence was much higher—almost double—in general hospital based acute units, compared with those sited in mental hospitals (9% vs. 5%). There was a negative relationship between the number of available adult acute beds and bed occupancy and there was also a relationship between levels of social deprivation, acute bed availability, and bed occupancy. Those services with low bed availability and high social deprivation therefore had the highest bed occupancy levels.

Despite these problems with overoccupancy, just over a one-quarter (27%) of current inpatients were judged not to require continuing admission and this proportion was significantly larger among those with admissions of more than six months. The most common reasons preventing discharge were the nonavailability of various community and residential options, in particular the lack of suitable supported housing. As might be expected, a lack of specialized rehabilitation places was seen as a more important reason preventing discharge for the new long-stay group. The higher prevalence of new long-stay patients in general hospital based acute units, compared with those based in mental hospitals, is consistent with the hypothesis that these patients are accumulating in acute units because of a lack of suitable alternatives. Those requiring higher levels of supervision in the form of secure accommodation (for reasons of violence) amounted to around 10%, although this proportion was higher (17%) among the new long-stay patients. The HoNOS severity scores were consistent with the staff judgments, thus validating the placement options selected by the staff.

These results therefore support the hypothesis that patients are now accumulating on acute admission wards who would previously have been accommodated on long-stay wards, in secure provisions, or in various community alternatives. The resultant shortage of acute beds seems to be related to both social deprivation and lack of bed availability. However, it is clear that a simple expansion of acute beds would not effectively address the problem. If all the patients who are judged to be inappropriately placed on acute admission wards could be relocated, then the problem of overoccupancy would effectively be solved. Acute units could then get on with the task of looking after the patients they are meant to be targeting (i.e., those whose needs are for immediate treatment and symptom stabilization). But this does mean the creation of truly comprehensive community services, with a spectrum of residential options geared to different levels of need and different kinds of problems. There are clearly considerable difficulties in achieving this, particularly in inner cities, with a background of poor housing, high unemployment, and other social problems.

Apart from new resources, the creation of comprehensive community services which can look after the most disturbed (and disturbing) individuals also implies a very considerable change in public attitudes towards the care of people with severe and enduring mental health problems. At the present time—at least in the UK—attitudes could hardly be less favorable. The inadequate development of community alternatives, combined with the reduction in long-stay beds, has led to some highly publicized failures of community care in which members of the public have been injured, or even killed, by people regarded as "mentally ill." The perception that community care has failed has been reinforced by sensationalist press and media coverage, although there is actually no evidence that the rate of homicides committed by people with a mental illness is actually increasing, nor that the care of those who committed these acts would have been improved if more psychiatric beds had been available. In reality, the problems seem to have been not so much due to a shortage of resources, but of a failure to coordinate resources effectively and to communicate between different agencies (Ritchie, Dick, & Lingham, 1994). It is thus the organization of services that has been deficient, not their basic structures (or even, in many cases, the overall level of resourcing).

As this new group of very disturbed and very difficult young people have begun to emerge, it has also become clear that traditional models of service delivery will simply not be effective with them. Many of these young people are very sensitive to stigma issues and are reluctant to engage with traditional services which they feel simply add to their sense of alienation and isolation. They want new forms of services—housing, work, etc.—which are not substantially different from those available to normal people. Furthermore, they want services delivered at the times and places most acceptable to them, rather than those which are most convenient for the professionals. Such services have been slow to develop and, as a result, some of these individuals have opted out of formal mental health care, sometimes with tragic consequences both for themselves and others. So, what can done to improve services for this group in the future?

6.23.5 SOCIAL AND PSYCHOLOGICAL DEFICITS

First, we must clearly understand the nature of their psychological and social deficits. In 1994, the UK Royal College of Psychiatrists' research unit reported on a national audit of new long-stay inpatients—those who had been in hospital continuously for more than six months, but less than three years (Lelliot & Wing, 1994; Lelliot et al., 1994). Almost two-thirds (62%) had a diagnosis of schizophrenia, half had more than five previous admissions to hospital, and just under one-third (29%) were detained under a Section of the Mental Health Act (mostly for compulsory treatment). They showed multiple disabilities, with a high prevalence of severe, treatment-resistant symptoms and a range of other behavioral problems (violence, self-harm, extreme antisocial behavior, etc.) which made them difficult to look after outside hospital. They tended to be socially unskilled, with poor work records, few family ties, and poor physical health. About one-third were judged to be capable of living in the community if highly supervised hostel placements were available, about one-third were deemed to require further treatment in hospital, and the remainder were so multiply handicapped that it was difficult to see where they might be placed.

A very similar pattern of results have been obtained from comparable populations in the US. For example, in a classic paper Sheets, Prevost, and Rehman (1982) hypothesized three subgroups among the new, "young chronics." The first group they described as characterized by "low energy/low demand" with long histories of contact with services, passivity, low motivation, poor personal hygiene, and treatment-resistant symptomatology. They appeared "burnt out," accepting of their status as "chronic" patients, despite their relative youth. The second group was termed "high energy/high demand" and these individuals were characterized by low frustration tolerance, high geographical mobility, rapidly fluctuating levels of functioning and symptoms, "acting out" behavior, aggression, contact with the law, etc. 5 > They were very demanding, uncooperative, and difficult to manage. Finally, there was a "high functioning/high aspiration" group, characterized by relatively good premorbid history, coming from the middle class, having high ambitions, but unable to realize them. They often also had significant problems with drug or alcohol abuse. This group were also rejecting of their status as chronic patients, but accepting of help from mental health services insofar as it would enable them to lead relatively normal, unstigmatized lives.

Gudeman and Shore (1984) also described the characteristics of patients in their service in Boston who had proved very difficult to look after in conventional community accommodation. They consisted of a mixture of elderly, demented people with behavioral disturbance (20%), mentally retarded persons with concomitant psychiatric illness and aggressive behavior (20%), people with acquired brain damage and loss of impulse control (10%), and two groups of predominantly schizophrenic patients, one with unremitting assaultive or suicidal behavior (17%) and the others who, while not being a frank danger to themselves or others, showed such unacceptable social behavior (e.g., disrobing in public, eating garbage, continually vomiting food at mealtimes) that they would not be tolerated in an ordinary community setting (33%). Similarly, Bigelow, Cutler, Moore, McComb, and Leung (1988) studied a group nominated as "hard to place" by staff in a state hospital. Almost three-quarters (70%) had a primary diagnosis of schizophrenia, often in association with drug and alcohol problems and almost two-thirds (62%) showed significant levels of violent and assaultive behavior. They also note the high prevalence of poor self-care, leisure, and social skills.

Thus, a consistent picture emerges, across very different settings and local conditions, of the psychological and social deficits found in people who are difficult to place in traditional services. First, there is a group of young men, almost all of whom have a primary diagnosis of schizophrenia, who show severe and intractable "positive" and "negative" symptoms and a variety of behavioral problems. They may also have concomitant drug or alcohol misuse. This is the largest group and, depending on local circumstances, is likely to account for between two-thirds and three-quarters of the total. Second, there is a group of older persons, primarily female, who are more likely to have treatment-resistant affective psychoses (depressed type or rapid cycling bipolar conditions) and who present a significant risk to themselves and may show extreme self-neglect when they are acutely depressed. They are likely to account for a further 20%. Third, there is an heterogenous group, usually having organic brain syndromes (acquired brain damage, presenile dementia, low IQ, alcoholism, etc.) again, often with other associated behavioural problems, sometimes also showing comorbidity with psychosis. They usually account for about 10%. What are the options for these groups in terms of models of service delivery?

6.23.6 MODELS OF SERVICE DELIVERY

The range of services necessary to meet this complex combination of needs, in the absence of large numbers of beds in mental hospitals, have been well described in a number of strategy documents published on both sides of the Atlantic (Department of Health, 1994, 1997; Stroul, 1986). At the center of these systems lie various forms of sheltered and supported housing.

It is something of a truism to state that without adequate accommodation effective management of those with the most severe and enduring mental health problems will not be achievable, but nevertheless it bears repeating. What is difficult is to specify the precise levels of the different kinds of accommodation that are required. Attempts have been made (e.g., Strathdee, Davies, Perry, & Thompson, 1996; Wing, 1992) but any general guidelines always require qualification depending on local circumstances. The greatest shortages are usually regarding high-support housing of various kinds, but the possibilities of substituting one kind of facility or service by another (e.g., intensive support teams instead of high-support housing) make "normative planning" difficult. Each location is different and each service therefore needs to evolve in order to fit the local conditions.

At the extreme end of the housing spectrum there are those individuals with severe and enduring mental health problems who are actually homeless, or in unstable, or very poor quality housing. The problem of severe mental illness among homeless populations has received considerable attention worldwide (Bachrach, 1992; Bhugra, 1996; Timms, 1993) yet there is still controversy concerning the link between reductions in hospital beds and apparently increasing numbers of mentally ill people among the homeless. Most of the evidence seems to point to an indirect link, with other factors—particularly general housing, benefit, and unemployment policies—also exerting a considerable influence. Thus, the typical mentally ill homeless person in the UK is actually young (i.e., under 30 years), with some degree of alcohol or other drug abuse, and a range of social and occupational disabilities in addition to their mental illness, but without a previous history of long admissions to psychiatric hospitals (Craig, Bayliss, Klein, Manning, & Reader, 1995). Often they may have had a series of short admissions (i.e., "revolving door") but generally do not have the characteristics of an old long-stay patient who has been turned out of a mental hospital. In terms of service provisions, apart from the obvious need for stable, good-quality housing, the most successful management approaches appear to be using specialist community teams, who practice an "assertive outreach" model (Dixon, Krauss, Kernan, Lehman, & DeForge, 1995). Breakey (1996) also notes four stages in providing psychiatric services for the homeless: (i) engagement; (ii) provision of basic services; (iii) transition towards mainstream services; and (iv) integration into ordinary housing and work programs. We will have more to say about the work of these kinds of specialist community teams later, suffice to say at this point that the contribution of clinical psychology to all these stages in terms of both assessment and management is very important.

As indicated, the goal of working with people with severe mental illness who are homeless is generally to try and get them into some kind of stable, sheltered, or supported housing. So, how can we judge the quality of care in such housing provisions? The principles underlying good-quality care in supported housing have recently been described by Shepherd (1998a). First, each person must be regarded as an individual with a unique set of needs and abilities. This is the antithesis of the "block treatment" which characterized traditional institutional settings (Goffman, 1961). Nobody should be given care that he or she does not need and, conversely, nobody should be denied help because of general rules or expectations regarding levels of functioning or performance. Staff should make use of their everyday observations of residents in a variety of community settings (shops, public transport, eating houses, etc.) to make direct assessments of their skills and deficits. Residents should be fully involved in the formulation of their own care plans and these should be reviewed—together with staff—at least weekly. The aim should be to create an active, information-rich, environment in which staff use their relationships with residents, in the context of collaboration over everyday activities, to shape behavior. In general terms, there should be an emphasis on practical tasks and daily living skills and a deemphasis of pathology. (This is not to say that symptoms or psychological distress should be ignored but, by definition, these residents will have exhausted most conventional therapeutic approaches.) The crucial question is, "To what extent do their symptoms interfere with their ability to function?" This emphasis on functioning rather than symptoms gives a clear "normalizing" message to residents and contributes to the maintenance of an ordinary household atmosphere.

Finally, staff should be encouraged to monitor the quality of their interactions with residents, as well as their quantity. Quality in this context means not only a respect for the individual, but also a style of interaction that conveys clear expectations about performance and tries to minimize criticism and censure. This may be characterized as a low EE style and follows from the recent evidence that high levels of criticism and hostility expressed by nonfamily carers may also be detrimental, just as within certain dysfunctional families (Ball, Moore, & Kuipers, 1992; Moore, Kuipers, & Ball, 1992). In terms of staff support, there needs to be an emphasis on consistency, continuity, teamwork, and communication. Maintaining a positive therapeutic environment is probably the most difficult task of all, staff need to meet regularly and continually to have the opportunity to review their work with each other and with senior colleagues. Teams are fragile and a lot of time and effort has to go into "feeding" them to keep them functioning at their highest level.

Next to accommodation, most service users place work and/or employment as their greatest priority (Rogers, Pilgrim, & Lacey, 1993; Shepherd, Murray, & Muijen, 1995). In terms of developing a comprehensive service, the aim must again be to provide a range of work opportunities—assessment and training, placement in open employment with support, sheltered social firms and cooperative businesses, etc.—to cover the range of users' needs (Grove, 1994; Pozner, Ng, Hammond, & Shepherd, 1996). Just as in housing, one should not expect everyone necessarily to "progress" through the system, acquiring more and more skills, and therefore requiring less and less support. Some will and some won't: and it is important to allow individuals to settle at their own "level." There must be opportunities to move on (e.g., toward open employment) but also opportunities to stay if this is more consistent with their abilities and aspirations.

Users particularly value services which they see as having a positive image and as being well regarded by others (Dick & Shepherd, 1995). It is thus insufficient that professionals regard a particular work program as representing good practice. The crucial question is, "Do users want to go?" If not, then it will fail to engage some of the most difficult, younger people with psychosis who actively reject conventional day and work programs. Of course, not everyone will want to engage in work programs, however attractive services try to make them—that's also fine. But we cannot afford to alienate users by offering services which essentially reflect the therapeutic interests and values of highly paid professionals, rather than what they say they want. In this connection it is worth remembering the classic study of Linn, Coffey, Klett, Hogarty, and Lamb (1979) which showed that the number of psychologists and other therapists was inversely correlated with a good outcome in day programs supporting people with schizophrenia in the community. Modern, relevant, high-status work activities—computing, silk screening, designing T-shirts, producing interesting looking booklets and newsletters—combined with loud music (and financial remuneration) may therefore be the necessary ingredients to attract many of the target group. If this is what is needed to give work programs a positive image, then this is what must be provided.

The Clubhouse Model (Beard, Propst, & Malamud, 1982) has also proved a very popular approach with some service users who are seeking a more positive image from mental health day care programs. The principles of this model are set out in Table 2. As can be seen, the clubhouse model emphasizes mutual cooperation and consensus between staff and members in the development of the program and the importance of meaningful occupation both within and outside the clubhouse. It has proved very popular, particularly in the US and, more recently, also in the UK and other parts of Europe (e.g., Sweden). However, it has not been without its detractors.

For example, Transitional Employment Placements (TEPs) have been criticized because of

Table 2 The principles of the Clubhouse Model.

It is a club and, as in all clubs, it belongs to those who participate in it
Members and staff work together to design and implement the clubhouse program
The clubhouse believes in the value and dignity of meaningful work activities
All members are made to feel on a daily basis that their presence is expected and that their attendance really makes a difference
There are never enough staff to run the program on their own: members' contribution is therefore necessary for the success of the program
Members have an opportunity to experience Transitional Employment Placements (TEPs). These offer fixed-term, part-time, entry-level work experience and may be used as stepping stone to paid employment
Membership is for life and the clubhouse is open seven days a week, 365 days per year

Source: Beard et al. (1982).

the restrictions placed on entry-level positions. This is necessary because the model demands that any member or staff person can, in principle, cover any position. As a consequence, it means that TEPs tend to be limited to very simple jobs and may therefore be unattractive to those seeking re-entry into highly skilled or professional careers. The style of shared decision-making between members and staff has also been criticized as not being genuinely participative and therefore not really "user led" (Chamberlain, 1988). Whether this is fair probably depends on the specific clubhouse concerned, but there is some evidence to suggest that users do feel involved and empowered in clubhouses and that this contributes significantly to their overall life satisfaction (Rosenfield & Neese-Todd, 1993).

Perhaps the most serious criticism of clubhouses is that the intentional community created by the clubhouse culture, while being very attractive to some individuals, may not be helpful to others in terms of their reintegration into mainstream social activities. There is clearly a dilemma here: on the one hand, the clubhouse provides a sheltered setting which protects vulnerable and disadvantaged people from the stresses of ordinary social contact—asylum in the best sense of the word. On the other, an asylum, however positive, may become difficult to leave and therefore runs the risk of creating an unhelpful dependency. There is no satisfactory answer to this dilemma (and, of course, it occurs in other models than the clubhouse). Services simply have to strive to strike a sensitive balance between shelter and independence and ensure that they have clearly permeable boundaries so that individuals do not become isolated and cut off from normal social life. This is a fundamental problem for all dedicated community services (housing, work programs, social programs, etc.) which provide specialized help and support in a segregated form.

Regarding social support, evidence has continued to accumulate that different individuals have very different needs in terms of social support and that these may vary significantly over time. For example, Cresswell, Kuipers, and Power (1992) demonstrated how people with severe negative symptoms may have less need for close emotional support, but greater need for more practical kinds of help. This is consistent with other evidence regarding the limited needs of some very disabled patients for close emotional support (e.g., Mitchell & Birley, 1983). In a classic paper, Brier and Strauss (1984) described systematic changes in social support needs as the people recovering from psychotic episodes progressed from convalescence in which reality testing, material help, social approval, etc. were the priority, through to rebuilding in which the attention shifted to motivation, reciprocal relations, and symptom monitoring. These considerations have led writers like Harris, Bergman, and Bachrach (1986) to stress the importance of "individualized network planning," that is, tailoring interventions much more closely to the individual's unique pattern of social needs.

In the social support literature, there has also been a change from a preoccupation with the size of social networks to an examination of the influence of other network variables, particularly their composition and density (i.e., interconnectedness). Thus, it has been known for some time that social isolation tends to be associated with a higher risk of admission, but it is now clear that repeated admission to hospital also affects the composition of the network. Over time, friends and relatives are gradually replaced by mental health professionals and other service users (Holmes-Eber & Riger, 1990). This is not only likely to lead to lowered levels of satisfaction with social supports (Goering et al., 1992) but may also create networks which are relatively poor at providing help in a crisis, since they are diffuse and lack the interconnectedness necessary to mobilize support quickly in an emergency (Dozier, Harris, & Bergman, 1987). Improving communication (interconnectedness) within support networks should therefore be one of the central goals for specialist community teams.

Specialist community teams are the glue that keeps services together around individuals and allows them to reach their potential while, at the same time, ensuring that they receive sufficient support. These teams were pioneered for the severely mentally ill by Leonard Stein and his colleagues in Madison, Wisconsin (Test & Stein, 1978) and have now been operating successfully for more than 25 years (Thompson, Griffiths, & Leaf, 1990). The model has been exported to Australia (Hambridge & Rosen, 1994) and several European countries (e.g., The Netherlands and Italy). Such teams are beginning to appear in the UK (Ford et al., 1995) but progress is slow. The model for these teams (including those that work with the homeless) is based on assertive outreach, with small caseloads (n = 10–15), extended hours of operation (i.e., outside Mon./Fri. 9–5), and the capacity to deliver intensive support (i.e., daily visits) where necessary.

It is important to distinguish between these "intensive support" teams and "crisis intervention" services. Although the two kinds of teams share some features in common (e.g., assertive outreach, extended hours, intensive visiting), the skills mix and methods of working are quite different. Thus, crisis teams tend to be focused on the short-term, with an emphasis on symptom resolution, whereas intensive support teams have a longer-term perspective, with more of an emphasis on support and the optimization of social functioning. Crisis teams are also much more reliant on the use of medication, and hospitalization, with the aim of rapid symptom stabilization, while intensive support teams give more emphasis to practical help, social support, and facilitating access to mainstream community activities.

The final element in the necessary range of services to support people with serious and enduring mental illness in the community are inpatient beds. No matter how good the specialist intensive support (or crisis intervention) teams are in the community, from time to time inpatient admission will continue to be required. Ideally, community and inpatient teams should work together as an integrated system, with the same medical input to both elements. However, there is often poor integration between hospital and community services and community teams may thus need to develop "assertive inreach" to the inpatient units, as well as "assertive outreach" to the community.

So, what is the evidence for the effectiveness of these different components of a comprehensive community service?

6.23.7 EFFECTIVENESS AND EFFICIENCY

There is a dearth of evidence regarding the effectiveness of different kinds of community accommodation. As indicated earlier, most long-stay patients show lower levels of symptoms (particularly negative symptoms), have better social integration, and report higher levels of satisfaction, compared with matched cohorts who remain in hospital (Leff, 1997). The higher levels of reported satisfaction among the community cohorts seem to be directly related to the less restrictive environments in community residential settings. This provides a link between quality of care measures and quality of life indices (Abrahamson, Swatton, & Wills, 1989; Shepherd et al., 1996). In order to improve the quality of life for people with severe and enduring mental health problems we therefore need to focus on changes which will increase their range of choices and opportunities in relation to simple, everyday life goals (e.g., meals and mealtimes, access to rooms and personal possessions, etc.). Even in some community settings this may be difficult to arrange: in hospital it is virtually impossible.

In terms of user preferences, it is quite clear that most patients prefer more independent living arrangements, combined with flexible staff support, rather than staff "on site" and having to live with a group of other people with severe mental illness (Tanzman, 1993). These aspirations are understandable, but may cause problems when it comes to the care of the most disturbed (and potentially "risky") individuals. It is clearly desirable to try to offer them placements in ordinary housing, but in practice this may heighten fears for their—and others'—safety. It may also provoke considerable resistance from the local community if they become aware that such developments are planned.

Because of these problems, the Department of Health in the UK has suggested the concept of "24 hour nursed beds" in an attempt to combine high levels of professional supervision with a relatively low degree of institutionalisation (NHS Executive, 1996). This idea is very similar to the concept of a "ward-in-a-house" or "hospital hostel" proposed some years ago as a solution for some of the most difficult new long-stay inpatients (Young, 1991). The evidence for the effectiveness of these models has been reviewed in Shepherd (1995) and more recently in Shepherd (1998a). It seems that they may be effective in improving the functioning of up to 40% of those referred sufficiently for them to be resettled into less highly supervised accommodation in the community after an average two to three years. Residents generally make more progress than controls regarding their social functioning, they show increased contact with the community, and higher levels of satisfaction. Again this seems to be associated with the increased privacy and choice associated with domestic scale living arrangements and the more "normal" atmosphere. For those who are not resettled, the units are more effective in maintaining their functioning than traditional long-stay wards or acute admission units. Costs are generally less than acute beds, but greater than long-stay wards in mental hospitals.

Despite these rather positive results, such options still remain unattractive to many of the people they are specifically designed to serve. For them, privacy, autonomy, and practical help with money, food, laundry, etc. may be much more important than professional support, medication, and considerations of public safety (Rose & Muijen, 1997). There is therefore a problem: on the one hand it is clearly desirable to go along as far as possible with users' expressed preferences, or we risk losing their trust and undermining their engagement with services. On the other, we need to ensure that the settings in which people are cared for are both cost-effective and safe. This is a real dilemma. The only way forward would seem to continue with the development of ordinary housing options, but combine this with intensive support from specialized teams (see below).

In relation to work and employment, the circumstantial evidence in favor of the effectiveness of work to favorable long-term outcomes for people with serious mental illness is very strong (Shepherd, 1997; Warner, 1985). However, the specific evidence in favor of the effectiveness of particular models of vocational rehabilitation—TEPs, social firms, cooperatives, "job coach" models, etc.—is rather weak (Grove, Frendenberg, Harding, & O'Flynn, 1997). Many of these projects are small scale and do not lend themselves easily to conventional random controlled trials. Hence, most of the available evidence consists of uncontrolled, descriptive studies (e.g., McCrum, Burnside, & Duffy, 1997; Nehring, Hill, & Poole, 1993). An interesting recent report concerns the employment of service users in various capacities within mental health services (Perkins, Buckfield, & Choy, 1997).

The best controlled evidence comes from the US and this has recently been reviewed by Bond, Drake, Mueser, and Becker (1997). They examined seven uncontrolled and six controlled studies of vocational rehabilitation programs and concluded that supported employment models were significantly more effective in achieving successful placements in competitive employment compared with conventional approaches (unweighted mean 58% for experimental programs vs. 21% for controls). They also suggest that "place-and-train" models seem much more effective than the more traditional "train-and-place" approach. Bond et al. emphasize the need to integrate clinical and vocational supports, as in the program described by Becker and Drake (1994).

The outcome evidence from controlled trials of specialist assertive community teams suggests that they can retain contact and improve levels of engagement with the most difficult and disabled people currently presenting to community services (Burns & Santos, 1995; Ford et al., 1996). The outcomes in terms of enhanced engagement and maintained contact are particularly important as loss of contact has been a common feature of the unfortunate incidents where community care has "failed." The use of inpatient admission can also be significantly reduced without any disadvantages in terms of symptom stabilization and control (Marks et al., 1994; Muijen, Marks, Connolly, Audini, & McNamee, 1992; Olfson, 1990; Taube, Morlock, Burns, & Santos, 1990; Wright, Heiman, Shupe, & Olvera, 1989). These effects on hospitalization rates are important, both in clinical and financial terms, and seem to be stronger with regard to reducing the number of days in hospital, rather than the number of admissions. Costs are generally slightly lower in the community treatment conditions compared with standard hospital care, mainly because of the reduction in hospital days (Muijen et al., 1992; Taube et al., 1990).

Satisfaction ratings on the part of both patients and families also tend to be much higher for these community-based interventions compared with standard hospital care and this persists even when other treatment gains may have been lost (Marks et al., 1994). This seems at least partly attributable to the reduced use of inpatient admission, underlining the unpopularity of acute hospital admissions among many service users. Increased satisfaction is also undoubtedly related to the greater input of time, better continuity of care, and more effective follow-up, which are central elements of successful intensive community support.

There is some variability in these results, but this is largely due to "fidelity" problems (i.e., failure to adhere to interventions of known effectiveness, see Section 6.23.8).

In relation to crisis intervention *per se*, Kluiter (1997) has reviewed the outcome evidence and, based on eight studies of home-based treatment, he estimated that the average number of days in hospital was less than a third (17:60) for the home-based treatment groups compared with the conventionally-treated inpatient groups. He concluded that various community alternatives (day treatment, home-based treatment, assertive case management, etc.) can produce at least equivalent outcomes to inpatient admission for the majority of those referred. Community-based services generally showed no difference with regard to symptomatic outcomes providing there was adequate access to accurate diagnosis and effective medication regimes, social recovery was usually quicker and, as with longer-term intensive support, user and carer satisfaction was enhanced. Not surprisingly costs were less where there were significant reductions in inpatient days (Knapp et al., 1994).

The evidence in favor of standard acute inpatient care is surprisingly limited. This is particularly striking given the fact that acute inpatient care generally accounts for about three-quarters of the total budget for most mental health services. As indicated, acute care has often been used as the "control condition" against which various community alternatives have been compared and it has seldom been found to be superior. Of course, it has to be acknowledged that most of these alternative community models (crisis teams, day hospitals, etc.) are quite selective in terms of who they will consider and there are some individuals who are simply too disturbed, too much of a danger to themselves or others, or too vulnerable in other ways, for admission to be avoided.

For example, Creed's evaluation of acute day hospital treatment suggested that inpatient admission was only feasible for approximately 60% of those referred (Creed et al., 1990). Similarly, in Hoult's famous study of community treatment in Sydney, 40% of the experimental group were actually hospitalized initially (compared with 98% of controls). However, the experimental group then went on to spend an average of only 8.4 days in hospital in the succeeding year, compared with 53.5 days for the controls (Hoult, Reynolds, Charboneau-Powis, Weekes, & Briggs, 1993). The aim of community-based models should therefore not be to avoid admission "at all costs": it should be to offer treatment in the least restrictive, and most appropriate, setting and in many instances this will be hospital. The more important question is then, "What kind of treatment do they receive while they are there?"

Geddes et al. (1996) studied all patients admitted to one ward over a one-month period ($n=43$) and found that less than two-thirds (65%) received medication regimes which could be said to conform to "evidence-based" practice. Regarding therapeutic interventions other than medication, researchers from the Sainsbury Centre for Mental Health (a research-oriented mental health charity in the UK) studied over 200 consecutive admissions across nine sites and noted a marked absence of evidence-based practice. The most common interventions for inpatients were "creative" therapies (art, drama, music–46%), social activities (33%), ward groups (23%), and relaxation (21%). Only 5% of the patients received any specific psychological therapies (Beardsmoore, personal communication) and there was essentially no sign of effective psychosocial interventions like CBT (Drury, Birchwood, Cochrane, & Macmillan, 1996a, 1996b) or EE-based family interventions (Linszen et al., 1996). The links between community and inpatient teams were also so weak that it was difficult for the ward-based staff to make valid assessments of the patients' needs and therefore to plan effective community management strategies. These rather depressing findings underline the gap which is still present in many acute settings between current practice and evidence-based regimes and highlight the important contribution that clinical psychologists might make to improving effectiveness in acute inpatient settings.

6.23.8 METHODOLOGICAL PROBLEMS

Regarding the outcome literature on models of community care, there are the usual methodological problems of poor sample definition, variable quality outcome measures, unexplained sample attrition, etc. (see Shepherd, 1998b). One of the more important issues concerns the paucity of long-term follow-up data. The problems of living with psychosis are, inherently, long term and it is therefore crucial that good data are available on long-term outcomes (even if this has to sacrifice some rigor in the design). Most complex psychosocial interventions tend to show a gradual diminution over time, particularly after the intervention stops. This is not surprising and simply demonstrates the importance of maintaining good continuity of care and an active state of treatment over long periods of time. Successfully managing psychosis is not like prescribing a course of antibiotics, it requires effective management strategies as well as effective treatment interventions (Shepherd, 1984).

Complex psychosocial interventions must also be given sufficient time to work. It is unreasonable to expect that significant improvements in housing status, occupation, or social networks can be achieved in three (or even six) months. Bond, Miller, Krumwied, and Ward (1988) note that such changes may take two to three years and that is important to give assertive case management programs a chance to settle down. Having said this, there are also examples in the literature of long-term effects of case management programs (e.g., McRae, Higgins, Lycan, & Sherman, 1990). It is certainly not the case that such programs cannot be sustained and that staff will inevitably burn out. As indicated earlier, the PACT program in Madison has been operating for more than 20 years and intensive support and crisis teams now cover most of the Australian states of New South Wales and Victoria. Sustainability is therefore not impossible but it depends on good training, support, and leadership. More will be said about this in Section 6.23.10.

A second major methodological problem concerns poor fidelity of the independent variables (i.e., the interventions themselves). Thus, whether it is a housing project, a work program, or a specialist treatment team, one often never quite knows to what extent the intervention being evaluated actually contains those elements which one would suppose, based on previous research, are likely to be associated with positive outcomes. Without a clear specification of the independent variable results, especially negative or "no-difference" results, it becomes very difficult to interpret and it is easy to conclude that a particular kind of intervention does not work when, in reality, it has never actually been tested. This problem is particularly important with regard to specialist community teams where some practitioners seem to believe that by simply calling a team intensive, or saying that it is practicing case management, means that this is what is actually happening.

In order to improve the "fidelity" of complex, community interventions, Teague, Drake, and Ackeson (1995) have set out some of the criteria that would need to be present in specialist, assertive, community teams if they are to adhere to models of known effectiveness. These are shown in Table 3. Such a list provides a convenient way for both purchasers and providers to check on the quality of the service being provided. If it does not match up to these criteria, then there is little reason to suppose that it will be effective.

The final methodological problem that it is worth highlighting is the magic ingredient without which these complex interventions do not seem to work. This seems to be different in different settings. In some cases it may be associated with the expertise or charisma of individual practitioners. In others it seems to be more a reflection of local conditions, "readiness to change," enthusiasm, staff morale, etc. In either event the literature is full of examples of apparently the same intervention which works in some places, but not in others (e.g., Bond et al., 1988; Creed et al., 1991). This phenomenon should not be dismissed as "Hawthorne effects" or "nonspecifics." It reflects the little understood processes of organizational change and development. If we could articulate and define it more precisely, then clearly we would be in a much better position to engineer more effective service change.

6.23.9 DEVELOPING A "USER-LED" SERVICE

The desire to involve users (and their carers) more fully in the process of service planning and delivery is now widely accepted, but most places are struggling to translate this laudable ambition into reality. How can we appropriately involve service users when their expressed wishes sometimes seem unrealistic, self-defeating, even frankly irrational? How can we appropriately involve service users when, under some conditions, we are prepared to deprive them of their liberty and force them to accept treatment against their will? How can we strike the right balance between the needs of users and those of carers when they often seem diametrically opposed?

These are not easy questions to answer. They touch on some of the basic moral and ethical dilemmas in psychiatry. They are certainly very difficult to answer in any general sense and are probably best addressed in relation to specific instances. However, historically, the voice of the user (and the carer) has been much neglected in psychiatry and there is therefore much to be done to redress the balance of power between user, carer, and professional opinions. There are signs that this is beginning to happen, but progress is slow. It is also clear that the involvement of users in making decisions about the content and structure of their care is now not just a matter of ethics and civil rights, it is a pragmatic necessity. Unless we can actively engage some of the most disturbed and disabled young people currently presenting to mental health services, then the consequences may be very serious for them and for others. We need to give them a stronger sense that services are for them and that they understand their needs and

Table 3 Ingredients of effective "high support" (assertive outreach) teams.

Small caseloads (n = 10–15)
Intensive contacts (1–2 hours/week)
Emphasis on "assertive outreach" (i.e., > 75% of contacts in community)
Team initiates all admissions to hospital (and discharges)
"Team" approach to sharing difficult clients (as opposed to strict "individual" case management)
Service not restricted to Mon.–Fri./9–5 pm
Regular (i.e., daily). team meetings
Clear operational management
Easy access to inpatient beds (preferably same RMO as community)

Source: Teague et al. (1995).

priorities. They need to feel some sense of control and "ownership" of their own care, even if—in extreme circumstances—this has to be taken away. So, what would mental health services look like if they were designed by service users, instead of clinicians and managers?

Finding out what users really think about services is not easy. First, there are problems with sampling and representativeness and care has to be taken to ensure that the group of users consulted does reflect the broad range of user opinion and is not simply constructed from those who are currently attending the service, or who are already active in local user groups. They are, by definition, biased groups and, although the views of "activists" are obviously important, they may not be representative of the "silent majority" of those who are not active (and possibly not very engaged) in the services they receive.

The method chosen to measure users' views may also significantly influence the results. For example, some qualitative approaches (e.g., focus groups) may give very different answers compared with paper-and-pencil questionnaires. Again, this is often attributable to the dynamics of small groups which favor those who are more assertive (and generally more "radical"). On the other hand, standardized, quantitative measures may be more easily replicable, but may lack the depth and "richness" of more qualitative approaches (and therefore have limited validity). A mixture of quantitative and qualitative methods is therefore preferable (see Mechanic, 1989). With careful sampling and multiple methods, it is therefore possible to survey users' and carers' views and then compare these with professionals' views. The results can then sometimes be quite surprising.

For example, Shepherd et al. (1995) asked over 400 patients, relatives, and professionals what they thought was most important for the care of people with schizophrenia in the community. The data were collected across six different districts, with a mixture of rural and urban settings. The patient and carer samples included some people who were contacted through mental health professionals (including a number who were not well engaged with current services) and others who were active in local user or carer groups. A mixture of quantitative (e.g., structured questionnaires) and qualitative methods (e.g., focus groups) were used. The results showed a reasonably good consensus between the three groups regarding what should be provided (housing, day care, symptomatic control, crisis planning, etc.) but significant differences between them regarding the relative importance attached to each element. Users emphasized the importance of practical help—housing, money, physical health care—while the professionals tended to rate professional interventions—treatment, support, symptom control, etc.—as being most important.

There were also some interesting differences between those users consulted through mental health professionals and those contacted through the local user groups. Both rated the provision of information about their individual disorders (diagnosis, treatment, outcome, etc.) and about services in general (availability of day care, accommodation options, etc.) as important; both also noted the difficulties of accessing professionals (or any other mental health services) outside normal working hours (Monday–Friday/9.00–5.00). However, as might be expected, the users who were active in user groups were much more radical in their views and more rejecting of services aimed at providing information about medication and "illness." They clearly did not wish to accept their status as "psychiatric patient" and therefore did not see the relevance of further information. In this respect, they were different from the majority of users and carers.

Findings such as these suggest that users do have different priorities from those of professionals or managers. If they were designing mental health services they would probably begin by addressing their basic needs—somewhere to live, something to do, and a decent level of financial support. They would then build clinical ("illness") services in around this framework. Given all the difficulties discussed earlier about the development of community services and the problems of interagency cooperation, even this seemingly simple prescription is not easy to meet.

The results also highlight the heterogenous nature of "user views." Just like nurses, doctors, or psychologists, there is no one, simple version of users' views. They differ depending on who is consulted and what methods are used. The involvement of users in service planning must therefore proceed on the assumption that there is no magic solution to the problem of user consultation. A variety of methods must be used, with a variety of groups, repeatedly over time. Perhaps most importantly, users must be given the opportunity to speak directly to professionals and be regularly involved in training and education programs. Only by regular, face-to-face contact, in a setting that allows users time to speak and professionals time to listen, can one be confident that the users' agenda will be kept in the foreground.

As indicated, one area in which the majority of users agree is regarding the importance of information about their disorders (causes, treatments, outcomes, etc.). By giving information the user is empowered to take a more active role in managing their own care just as in the management of a long-term physical health condition like heart disease, diabetes, or asthma. The aim is to provide information and support so that those affected can manage their own disorder as much as possible and prevent the accumulation of secondary disabilities. Of course, this approach will not work with everyone (it does not work with all those suffering from diabetes or coronary heart disease) but it does imply a fundamental shift in attitude (and power) away from the professional and towards the patient and his/her family or other carers. The role of the professional is then to be "on tap, not on top" providing expert knowledge and support, but not taking away from the individual their ultimate responsibility for their own health care and its management.

If professionals are going to be able to function in this new kind of role, then they will have to be prepared to share information and knowledge in a much more open way than has been common in mental health services up to now. For far too long mental health professionals have been overly secretive about what they do and why. They have felt uncomfortable about trying to answer straight questions like "Why did I get ill? Will I get better? What do I have to do to prevent another breakdown? Sometimes this is because they simply do not know, not surprisingly, since these are very difficult questions. Sometimes they may feel that their credibility will be undermined if they reveal a degree of ignorance (despite the fact that most patients would prefer an honest answer to defensive interpretation). But sometimes they may rationalize their silence by appeals to confidentiality and professional values. In effect, whether consciously or unconsciously, they are then using their access to information to maintain their position of power and authority. A psychoeducational approach fundamentally challenges this position. Except in very special circumstances, a psychoeducational model assumes that patients have a right to know what professionals think they know about them and why they intend to treat or manage them in particular ways—whether they agree with this or not. An educational model is thus very different from a therapeutic model: good teachers aim to empower their students by sharing their knowledge and skills, not disempower them by concealment and manipulation.

To date, the evidence in favor of the effectiveness of psychoeducational approaches is mixed. There do seem to be some measurable gains in knowledge resulting from the provision of simple, clear information to both users and carers, but the increases tend to be small and are heavily influenced by the receiver's preconceived ideas (Sidley, Smith, & Howells, 1991; Smith & Birchwood, 1987; Smith, Birchwood, & Haddrell, 1992). Psychoeducation thus seems to work best when integrated with a comprehensive psychosocial "package," including problem-solving, skills training, etc. (e.g., Hogarty et al., 1991). At the heart of psychoeducational packages is an attempt to help the person—and their immediate carers—recognize the early warning signs of possible relapse and intervene accordingly (Birchwood et al., 1989).

It has been recognized for some time that many patients do not relapse suddenly into a psychotic state. Most go through a "prodromal" (i.e., prepsychotic) period, often characterized by an increase in neurotic symptoms (agitation, sleeplessness, poor concentration) before clear psychotic symptoms appear. Around two-thirds of people with relapsing psychosis can accurately report these early warning signs and over three-quarters of relatives and other carers (Herz & Melville, 1980). Furthermore, the particular pattern of symptomatic changes is often highly specific to each individual patient: they might therefore be said to possess a kind of personalized relapse "signature" (Birchwood, Macmillan, & Smith, 1992). The potential importance of identifying such relapse signatures is obvious. Close monitoring of prepsychotic symptoms may enable patients and clinicians to work together much more effectively and thereby manage with significantly lower overall doses of medication. Since the prevalence of drug side effects is very much related to the size of the dose, and since for many patients it is the severity of side effects which most significantly influences their decision to continue (or not) with medication, these approaches hold out considerable promise in improving medication compliance and delivering the maximum positive benefits from pharmacological interventions while minimizing their adverse side effects.

Other psychological approaches to improving compliance by involving users more fully in their own treatment and management plans have now also been developed (e.g., Corrigan, Liberman, & Engel, 1990; Eckman, Liberman, Phipps, & Blair, 1990; Eckman et al., 1992). One of the most interesting is the application of a technique known as "motivational interviewing." This was originally formulated to assist people with tackling problems of drug or alcohol abuse and is based on the assumption that most important behavioral choices contain some element of conflict (e.g., "How do I weigh up the immediate benefits of alcohol or other drug consumption against its longer-term ill effects ?"). In the case of medication compliance in schizophrenia, the question is, "How do I weigh up the degree of symptom relief associated with taking my medication, as opposed to the clear disadvantages in terms of side effects—lethargy, tiredness, weight gain, loss of libido, etc.?" The motivational interviewing intervention is built around a structured exploration of these conflicted beliefs and an effort is made to encourage maximum personal commitment to whatever final decision is reached (Miller & Rollnick, 1991). Results from a random controlled trial using this approach suggest that such interventions cannot only improve compliance and enhance symptomatic outcomes, they can also increase community tenure up to 18 months postdischarge (Kemp, Hayward, Applewhaite, Everitt, & David, 1996). Such results are very encouraging and one would hope to see more of these new approaches aimed at addressing some of the psychological issues around medication compliance. The effectiveness of medication in the treatment and management of severe mental illness is, after all, as much determined by the psychological decisions surrounding the decisions to take it (or not) as it is about its pharmacological action.

A psychoeducational format therefore involve users in their own care in a way that is quite different from the traditional patient–therapist relationship. The therapist talks openly about symptoms, he/she acknowledges that these experiences are not uncommon, and that it isn't therefore just a personal nightmare. The individual is thus helped to develop a new "relationship" with their disorder. Instead of being, "a schizophrenic," they become, "a person who is trying to manage their schizophrenia," not a schizophrenic. There is a parallel here with people with anxiety or depressive symptoms who develop a different relationship with their symptoms as a result of successful treatment. They start to see the possibility of exerting some degree of control over these painful and distressing experiences, rather than being controlled by them. This can be the basis for a more positive adjustment to their condition.

6.23.10 STAFF TRAINING

All this implies some very fundamental changes in the way that mental health professionals are currently trained and supported. What do we need to make staff more effective in working with people with severe and enduring mental health problems?

First, we need to ensure that they are able to deliver the range of psychosocial treatments of known effectiveness. We have emphasized throughout this chapter that rehabilitation must proceed from a basis of effective treatment, yet it is still rare to find staff who are well enough trained to deliver the full range of psychosocial interventions that have been demonstrated to be effective with this client group. For example, despite the familiar problems of lack of generalization and maintenance, traditional skills training models clearly have some value in promoting the acquisition of social and other skills (Corrigan, 1991). The effectiveness of skills training models are also likely to be enhanced if they are combined with suitable medication regimes, behavioral family management programs, and psychoeducational approaches (Hogarty et al., 1991). Similarly, the evidence for the effectiveness of EE-based family interventions in preventing—or at least postponing—relapse in schizophrenia is now very strong (Barrowclough & Tarrier, 1998; Mari & Streiner, 1994), again particularly in combination with medication and psychological interventions. Finally, CBT has produced some promising evidence for its effectiveness in terms of reducing symptom severity and alleviating some of the subjective distress associated with residual psychotic symptoms in outpatient samples (Kuipers et al., 1997) and, as indicated earlier, there are some very interesting reports of CBT applied in inpatient settings resulting in significantly more rapid symptomatic recovery and reduced overall lengths of admission (Drury et al., 1996a, 1996b). There is thus a very strong evidence base for the effectiveness of a number of psychological approaches and a considerable task to be done in terms of training and supporting staff to implement such interventions.

Staff must also be prepared to deliver care which is sensitively tuned to the "user agenda." As indicated earlier, this means that services have to be delivered much more on the user's terms and much less according to a "professional view" of what is most important. This can be difficult for those staff with a strong desire to show off their therapeutic skills, but there is a kind of "higher professionalism" which recognizes that sometimes sorting out someone's housing benefits and finding them meaningful work is more important—and makes a better starting point—for a therapeutic relationship than delivering "state-of-the-art" cognitive-behavioral intervention for residual psychotic symptoms, or detailed assessments of cognitive functioning, self-care skills, etc.

Staff must also be credible. What makes staff credible will be different for different users: some may prefer younger workers, some may prefer older, some may prefer the same gender, same ethnic group, etc. Whatever their background, users must feel that the worker has a real understanding of their situation and is able to offer something constructive to help. Teams therefore require a mixture of ages, backgrounds, experience, etc. Some users may even prefer staff who themselves have direct experience of receiving mental health services and there are some interesting examples from the US of service users receiving training and then acting as case managers (e.g., Mowbray et al., 1996; Solomon & Draine, 1995).

But it is not sufficient that staff simply have an intellectual understanding of users' problems, they must be able to empathize with their situation and convey this effectively. Users should also feel that staff like them (at least most of the time!). Sensitivity, humor, honesty, warmth may all sound like cliches, but they are central to forming effective working relationships in this, as in any other, form of therapeutic activity. Users may need to be seen in their own homes, in the street, in shops, the park, the pub, and the cafe. Staff need to be prepared to work outside normal offices and formal facilities; they must be prepared to work alongside the user in a variety of apparently mundane activities and recognize that these are all vital opportunities for assessment and treatment. They must be creative in their ability to exploit these contacts and to extract the maximum therapeutic benefit from what may often be unconventional encounters. Staff must also be very clear about the limits of their own competence (whatever their specific areas of expertise) and be prepared to enlist the help of colleagues from the same or other agencies (e.g., in housing, employment agencies, etc.) who also have expert knowledge in their own fields. This openness to working with others and clear recognition of one's own limitations are key ingredients for effective staff working with this client group.

Can we say anything more about the kind of personality that we should be looking for? As indicated earlier, the concept of low EE has recently been extended to staff and other informal carers (Ball et al., 1992; Moore et al., 1992) and this forms a useful framework for thinking about staff characteristics. It is a common clinical observation that staff often make the same "blame attributions" for negative symptoms which seem to underlie the responses of high EE relatives (Brewin, MacCarthy, Duda, & Vaughn, 1991). It is therefore possible that the same kinds of educational and skills-based programs that have been developed for families (e.g., psychoeducation, problem-solving, communication training, etc.) may be equally relevant for staff (Ranz, Horen, McFarlane, & Zito, 1991). Low EE staff will not get too irritated or frustrated in the face of repeated failure and avoid blaming the patient for his or her difficulties. This does seem to be related to a particular kind of personality type, but may also be facilitated by having clear and realistic expectations for change, which in turn is based on good support and supervision.

Effective leadership, organization, and management of staff are therefore also crucial. Leaders can be from any discipline, but they need both good analytic skills (to break down problems, set priorities, assign tasks, etc.) and good socio-emotional skills (to involve and support others, develop a strong sense of common ownership, commit them to carrying out agreed actions, etc.). There is a strong consensus now regarding the importance of team case management systems, as opposed to individually-based case managers (Stein, 1992; Test, 1979). Obviously, there have to be clear individual accountabilities, but this does not remove the necessity for good teamwork and sharing of responsibilities—and, to a certain extent, clients—within the team. This is necessary to cover for staff when they are absent or unavailable. Effective teamwork is really the only way in which good continuity of care can be maintained.

In the UK, the management of community teams has been identified as an important area of weakness (Onyett, Pillinger, & Muijen, 1994). This has been partly attributed to a lack of managerial authority on the part of team leaders, related to the continuing tension between professional and operational management. The outcome of this confusion is a lack of clarity regarding the roles and accountabilities of individual staff and this is associated with feelings of dissatisfaction and emotional exhaustion (burnout). Onyett et al. argue that in order to counteract this, team leaders should have clear managerial authority over operational matters (i.e., day-to-day running of the team) even if this means weakening professional line management. This may be controversial in some countries, but seems necessary if teams are to function effectively.

In the end, teams are delicate and complex structures. They require good training, good leadership, good organization and management, and good support. None of these components can be ignored if they are going to function to their maximum effect.

6.23.11 CONCLUSIONS

This chapter has covered a considerable range of topics. The effective treatment and management of people with severe and enduring mental health problems raises issues at all levels of services—individual, team, facility, subculture—and these are played out differently in different countries with differing social conditions, welfare systems, levels of unemployment, etc. In my view, this is what makes rehabilitation such a rich and intellectually challenging field and there is much that clinical psychology has contributed to the analysis and solution of these problems. But clinical psychology will never be enough on its own. Psychologists have to learn to work with other professionals—doctors, nurses, social workers, occupational and vocational therapists—and a range of social scientists—medical researchers, sociologists, economists—to produce integrated strategies to address these complex problems.

At their heart remain the experiences of patients, staff, and families. People with severe and enduring mental health problems the world over are still waiting to see services emerge which will effectively address their very basic—and seemingly very simple—needs. Somewhere to live, something to do, and a decent level of financial support. These do not seem unreasonable, or unrealistic, demands, but it is still rare to find them completely met. Similarly, staff need to be trained in effective interventions and then organized and supported in such a way that these can be delivered in the most efficient way possible. Again such conditions are rarely met. Finally, there are families and other carers. Families provide more health care than any formal system of professional care ever does, or ever will do, and severe and enduring mental illness is no exception. Yet families are still often ignored, seldom consulted, and sometimes even blamed for being the cause of the problem. It is not surprising that many are frustrated to the point of bitterness, asking "How long will it be before we are treated as genuine *partners* in care?" As professionals we have a responsibility to respond to this question and to ensure that families are included in the process of care and not simply exploited as a convenient (and cheap) resource.

So, there is much to be done. But, nevertheless I am optimistic. I believe that systems of care for people with severe and enduring mental illness have generally improved over the last 40 years and there are some outstanding examples, in several countries, of truly comprehensive, community-based services which do address peoples' housing, vocational, social, and clinical needs. Our task is to make these the norm rather than the exception. To achieve this, we must combine what the Italian philosopher Gramsci referred to as, "The optimism of will, tempered with the pessimism of reason." This is surely the task for the next millenium.

6.24.1 CLINICAL PICTURE

Many individuals present to medical practitioners with physical complaints for which no medical explanation can be found. For instance, a European study (van Hemert, Hengeveld, Bolk, Rooijmans, & Vandenbroucke, 1993) found that among 191 new referrals to a general medical outpatient clinic, 52% of patients had symptoms that ultimately remained unexplained. An earlier Australian study reported that of 95 patients visiting a general practitioner and presenting with somatic complaints, 41% had no demonstrable somatic pathology (Pilowsky, Smith, & Katsikitis, 1987). Comparable percentages have been reported in other studies from different countries investigating unexplained symptoms of patients with abdominal pain (Harvey, Salih, & Read, 1983) and chest pain (Eifert, 1992; Mayou, Bryant, Forbar, & Clark, 1994).

Although many of these patients will be satisfied with negative medical examination results, and some reassurance to that effect, a significant subgroup will anxiously continue to ruminate about the possibility of suffering from a yet-undiagnosed physical disease. They are likely to continue to seek help for the same or different physical symptoms, demand more physical examinations and specialist referrals, undergo costly laboratory tests, and, in some cases, even end up on an operating table (Warwick & Salkovskis, 1990). Despite the high prevalence of ambiguous and unexplained physical problems, somatoform disorders have received only minimal research attention and are poorly understood. A major reason for this relative lack of knowledge is that persons with such problems are typically reluctant to see a psychologist and prefer to remain within the medical service system. As a result, they have literally evaded the attention of clinical psychologists.

We have organized our discussion in this chapter around the categories and classification put forward in the *Diagnostic and statistical manual of mental disorders* (4th ed., *DSM-IV*; American Psychiatric Association [APA], 1994). There is considerable overlap between somatoform disorders and several of the anxiety disorders. We will therefore make an attempt to move beyond *DSM* categories toward a more function-based dimensional perspective of the problems of persons who present with either unexplained somatic symptoms or excessive concerns over physical symptoms. We believe that such an approach is clinically more beneficial because it provides information that is directly useful for the design of clinical interventions.

6.24.1.1 *DSM-IV* Classification

The present classification of somatoform disorders stems from the *DSM-III* taskforce decision to eliminate the concept of neurosis because of its etiological connotations. This change resulted in disorders previously classified in one category as neuroses (anxiety neurosis, neurotic depression, hypochondriasis, and hysteria) to be redefined and reclassified in four separate *DSM* categories: anxiety disorders, mood disorders, somatoform disorders, and dissociative disorders (Murphy, 1990). According to *DSM-IV* (APA, 1994), the common feature of the somatoform disorders is the presence of physical symptoms that suggest a general medical condition (hence, the term somatoform) but are not fully explained by a general medical condition, the direct effects of substance, or by another mental disorder. Physical symptoms result in substantial personal, social, and occupational impairment, and are not feigned or voluntarily produced, as in malingering or factitious disorder.

DSM-IV distinguishes between six somatoform disorders: somatization disorder, undifferentiated somatization disorder, conversion disorder, pain disorder, hypochondriasis, and body dysmorphic disorder. These disorders can be categorized under two larger headings of the classical "hysterical disorders" and "preoccupation disorders." Hysterical disorders involve actual loss or alteration in bodily functions as in the case of somatization disorder, conversion, and pain disorder. Reports of suffering often exceed symptom reports of patients with known medical illnesses. Patients with hysterical disorders typically experience no anxiety, whereas persons with preoccupation disorders are excessively concerned that there is something physically wrong with their body either in terms of disease (hypochondriasis) or in terms of the shape and size (body dysmorphic disorder). The general features of each of these disorders will be outlined below.

Somatization disorder is characterized by multiple physical complaints without clear or known physical causes. The condition may last for many years and, in some cases, extend over the entire adult life-span. To make the diagnosis, an individual needs to present with a history of pain related to at least four different sites or functions (e.g., head, back, abdomen, joints), two gastrointestinal symptoms (e.g., diarrhea, food intolerance), one sexual symptom (e.g., irregular menses, indifference to sex), and one pseudoneurological symptom (e.g., poor balance, numbness, paralysis). These symptoms lead to frequent and multiple medical consultations, complex medical history, and to alterations of the person's lifestyle. Physical and laboratory findings cannot detect a plausible medical condition to be the cause of the symptoms, and if a cause exists, the patient's reaction seems to be in excess of what would be expected.

Hypochondriasis is characterized by unjustified fears, suspicions, or convictions that one has a serious and often fatal illness such as heart disease, cancer, or acquired immune deficiency syndrome (AIDS). Patients frequently seek reassurance, check their bodies, and avoid illness-related situations. Merely informing patients of the absence of a disease process, or explaining the benign nature of the symptoms, only results in temporary reassurance which is followed by renewed worry over symptoms and continuing overuse of medical services (Salkovskis & Warwick, 1986).

Pain disorder is characterized by severe acute or chronic pain in one or more body parts. The pain is not easily understood, or cannot be fully accounted for, by a known medical condition. Pain is *ipso facto* a subjective phenomenon and psychological factors such as mood, anxiety, and attention may be involved in the onset, maintenance, or exacerbation of pain and complicate differential diagnosis. Pain is considered acute when it exists for less than six months and chronic when it persists beyond six months. Chronic pain, in particular, is often associated with major changes in behavior such as decreased activity and somatic preoccupation (Pilowsky, Chapman, & Bonica, 1977).

Conversion disorder is characterized by symptoms suggesting a neurological disorder, although appropriate medical investigations fail to identify a neurological or general medical disorder. At times, symptoms may even be inconsistent with general neurological knowledge. *DSM-IV* describes four subtypes with (i) motor symptoms or deficits (e.g., paralysis), (ii) seizures of convulsions, (iii) sensory symptoms or deficits (e.g, blindness, anesthesia, and aphonia), and (iv) a mixed presentation. Some patients show an indifference or lack of worry about their symptoms (*la belle indifference*). An important requirement for the diagnosis is the temporal relation between conversion symptoms and a psychological stressor such as acute grief or victimization. Patients are typically unaware of the psychological basis for their symptoms and report being unable to control them.

Body dysmorphic disorder (BDD) is characterized by a preoccupation with an imagined or exaggerated body disfigurement or an excessive concern that there is something wrong with the shape or appearance of one's own body parts. The perceived defect or abnormality is generally not or hardly noticeable to others. Objects of concern typically refer to the face (nose, mouth, eyes, teeth), head (hair thinning), sexual characteristics (size of penis, breasts), or general body appearance (too long or too short, ugliness). Other concerns may involve scars, wrinkles, or body odor. Cognitive features are excessive preoccupation, intrusive thoughts, and sometimes ideas of reference. On a behavioral level, features include avoidance (e.g., of body exposure, direct social contact, talking about the problem, looking in the mirror), camouflaging or concealing of imagined deformities (wearing a hat or glasses), excessive grooming and checking, and reassurance seeking.

6.24.1.2 Disease, Illness, and Somatization

Disease is often described as the presence of objective biological abnormalities in the structure and/or function of bodily organs and systems. Illness refers to the subjective perception of being unwell, and may be unrelated to the presence of an objectifiable disease. The sick role is a sociological construct initially put forward by the American sociologist Talcot Parsons pertaining to a role granted to an individual by society with accompanying privileges (e.g., staying home from work) and obligations (complying with medical regimens).

Pivotal to the somatoform disorders is the phenomenon of somatization, defined by Lipowsky (1988, p. 275) as "a tendency to experience and express psychological distress in the form of somatic symptoms which the individual misinterprets as significantly serious physical illness and seeks medical help for them." Rather than referring to a discrete group of disorders, this definition reflects the current opinion of somatization as a complex psychopathological process that may be involved in a variety of clinical problems (cf. Kellner, 1986).

Psychosomatic disorders have traditionally been regarded as medical conditions in which psychological factors play a role. The concept of psychosomatic disorders is misleading, however, because it presupposes a special class of somatic disorders of psychogenic etiology (Lipowsky, 1988). A conceptually more neutral concept is that of "functional somatic symptoms," which Kellner (1986) defined as somatic symptoms that are not attributed to organic pathology demonstrable by physical examination or routine laboratory tests—although transient physiological changes may be found in some of the disorders or can be detected by special techniques such as measurement of bowel contractions or of changes in striated muscle tension.

Conceptual proliferation and confusion dominate the field of somatization and somatoform disorders. Many concepts are used interchangeably or remain ill-defined in research and clinical practice. Despite considerable comorbidity, and even phenomenological overlap between psychological and somatic disorders, Cartesian dualism is still implicitly or explicitly influential in clinical practice. This may, in part, be due to the traditional division of labor between medical and psychological disciplines, each claiming (or hoping) to answer some of the questions in the mind–body realm. Such reductionist models, however, are a serious obstacle to a more comprehensive understanding of somatoform disorders.

6.24.2 HISTORICAL PERSPECTIVES AND DIAGNOSTIC CHANGES

Early views of somatoform disorders assumed that these disorders have common roots and are somehow related to the female reproductive system. The French neurologist Charcot (1825–1893) demonstrated that "hysterical conversions," involving symptoms such as convulsions and paralysis, could be induced by hypnotic techniques. He assumed that conversions originate from mental rather than physical processes. Physical symptoms were regarded as a defense mechanism against unacceptable unconscious conflicts where massive repression forces psychic energy to be transformed into bodily symptoms. Although specific psychodynamic notions have been eliminated from the current *DSM-IV*, conflict is still believed to be involved in some of the somatoform disorders. For instance, in the case of conversion disorders "psychological factors are judged to be associated with the symptom or deficit because the initiation or exacerbation of the symptom or deficit is preceded by conflicts or other stressors" (APA, 1994, p. 457).

6.24.2.1 Somatization Disorder

Somatization disorder is the current term for what is arguably the oldest mental health diagnosis, "hysteria." More than 2000 years ago, the ancient Greeks believed that multiple somatic symptoms were caused by the uterus wandering through the female body. In the middle of the nineteenth century, the French physician Briquet described a polysymptomatic somatic condition ("Briquet's syndrome"), which was redefined in the 1950s as somatization disorder (cf. Bass & Murphy, 1990) and became the basis for the current diagnostic entity.

6.24.2.2 Hypochondriasis

Hypochondriasis is a Greek word meaning "below the cartilage." The ancient Greeks derived the concept of hypochondriasis from humoral theories of disease and considered it a special form of melancholia resulting from an excess of black bile. In the seventeenth century, Thomas Sydenham, an English physician, argued that hypochondriasis occurred only in men and was equivalent to hysteria occurring in females. Also around this period, Descartes proposed that the mind and body were separate entities, and there could be no causal relation between the two. Subsequent psychodynamic views suggested that hypochondriacal patients direct their libido inwards, whereas healthy persons typically direct their libido at external objects. Eventually, internally directed libido would build up and result in physical symptoms (Freud, 1956).

6.24.2.3 Pain Disorder

Throughout history, there has been considerable speculation concerning the nature and cause of pain. For instance, Aristotle viewed pain as an emotion as opposed to a sensation, Descartes viewed it as a result of physical stimuli impinging upon the body, Epictetus viewed it as the result of cognitive activity, and religious leaders viewed it as a test of faith imposed by god or punishment for sins (Turk, Meichenbaum, & Genest, 1983). A commonality of these early theories was a unidimensional view of pain. Theories were based either upon organic or psychological causes, and few attempted to integrate the two. It was not until the twentieth century that Cartesian dualism was seriously questioned and multidimensional theories of pain began to develop.

6.24.2.4 Conversion Disorder

The origin of the contemporary concept of conversion disorder can be traced back to the Middle Ages when "conversio" referred to diseases caused by a "suffocation of the womb." Freud considered conversion a form of defense in which the resulting symptoms were fixations of physical patterns relating to events at the time of a patient's (sexual) trauma (Mace, 1992). Primary gain was seen as the warding off of these forbidden impulses, whereas secondary gain was the attention and privileges patients received. The loss of bodily functions in conversion disorder was thought either to be the direct effect of the trauma or to symbolize the unconscious conflict.

6.24.2.5 Body Dysmorphic Disorder

The term "dysmorphophobia" was coined in the late nineteenth century by the Italian psychiatrist Enrico Morselli (cf. Berrios & Kan, 1996). Based upon his clinical observations, Morselli described a condition in which there is a sudden onset and subsequent persistence of an idea that the body is (or might become) deformed. Morselli stressed the obsessive nature of this condition and the strong desire to check the perceived body abnormality. Although Morselli described his patients as being fearful about their deformities, more recent investigations (e.g., Fava, 1992a) could not substantiate the presence of phobic anxiety in this condition. As a result, the term dysmorphophobia was abandoned in *DSM-IV* and replaced with the diagnosis of body dysmorphic disorder (cf. Bass & Murphy, 1995).

6.24.3 PREVALENCE, COURSE, AND DEVELOPMENT

There is a preponderance of studies showing that the presentation of symptoms for which no demonstrable organic pathology can be found is a common occurrence in a variety of medical settings (Pilowsky et al., 1987; van Hemert et al., 1993). Yet the exact prevalence of somatoform disorder is still unclear. This is largely due to the fact that studies frequently did not adequately differentiate between somatoform and related disorders (e.g., anxiety, depression), and epidemiological studies have used various diagnostic criteria and different samples (cf. Kellner, 1986). Although systematic knowledge is lacking, factors such as parental rearing and childhood development, stressful life events, high negative affect, and aspects of the relationship and communication between patients and doctors have been related to the development of somatoform disorders (e.g., Bass & Murphy, 1990; Craig, Boardman, Mills, Daly-Jones, & Drake, 1993).

6.24.3.1 Somatization Disorder

Somatization disorder is a relatively rare phenomenon with recent community studies citing prevalence rates between 0.4% and 0.7% (cf. Bass & Murphy, 1990). Its onset is in early adulthood, course is often chronic, and prognosis is generally regarded as poor. Somatization is associated with frequent absences from work or school, overuse of medical care, and excessive use of drugs and alcohol (APA, 1994). In recent years sexual abuse and traumatization have been cited as a precursor of somatization disorder (Salmon & Calderbank, 1996). For instance, female psychiatric patients with somatization disorder have reported more sexual and physical abuse than patients with other disorders (Pribor, Yutzy, Dean, & Wetzel, 1993).

6.24.3.2 Hypochondriasis

Most prevalence research related to hypochondriasis has been conducted in some type of medical or psychiatric setting and results have been inconclusive (cf. Iezzi & Adams, 1993). Research has been impeded by the use of different definitions of hypochondriasis. For example, Kenyon (1976) used a strict definition and determined that 3–14% of patients in a medical setting were hypochondriacal. With regard to illness fears, Agras, Sylvester, and Oliveau (1969) interviewed 325 randomly selected subjects from the general population and found that 16% had fears of illness and 3.1% qualified as having an illness phobia. Moreover, individuals with frequent exposure to medical settings (e.g., medical students) appear to have increased health concerns (Hunter, Lohrenz, & Schwartzman, 1964; Jacob & Turner, 1984). The onset of hypochondriasis is frequently in early adulthood. Although symptoms may wax and wane, the course is typically chronic and the condition frequently takes a dominant role in the person's life and relationships.

In children, somatic complaints and attention to physical symptoms have been shown to be influenced by attention received from parents (Mechanic, 1964). In addition, adult patients who rate themselves as having high hypochondriacal concerns describe their parents as more caring and overprotective than patients with other psychiatric disorders (Parker & Libscombe, 1980). Studies also found that somatic symptoms of child and adult hypochondriacal patients resemble those of their parents (Apley, 1958). An individual's perception of and exposure to physical symptoms and disease in the family, in combination with parental attitudes towards illness influencing the development of hypochondriacal concerns in children (Eifert, 1992; Flor, Birbaumer, & Turk, 1990; Kellner, 1985). These concerns are likely to continue into adulthood, particularly when persons experience symptoms that they cannot easily explain or understand. For instance, Eifert and Forsyth (1996) found that exposure to heart disease in parents may make observing children more vulnerable to developing fears of heart disease. Furthermore, the death or terminal illness of a relative or friend has also been shown to precipitate hypochondriacal fears and behaviors with developing symptoms often resembling the deceased relative's symptoms (Eifert, Hodson, Tracey, Seville, & Gunawardane, 1996; Parkes, 1972). Finally, sexual trauma has also been linked to the development of excessive health anxiety. Barsky, Brener, Coeytaux, and Cleary (1995) found that hypochondriacal hospital outpatients recalled more childhood trauma (parental upheaval, sexual trauma, and beatings) before the age of 17 years than a patient control group.

6.24.3.3 Pain Disorder

The exact prevalence of pain disorder is unknown, but it appears to be relatively common and may occur in adults of all ages. For example, pain is the most common complaint of individuals presenting to a physician (Ford, 1995). The proliferation of special pain clinics could be seen as another indication of the high number of pain patients seeking professional help. According to *DSM-IV* (APA, 1994) estimates, in any given year, 10–15% of adults in the United States have some form of work disability due to back pain alone. A study of internal medicine private practice patients found that 13% of patients suffered from chronic pain (Margolis, Zimny, & Miller, 1984). Using a sample of HMO enrollees, von Korff, Dworkin, and LeResche (1990) observed that 45% of individuals reported persistent or recurrent pain with 8% reporting severe pain and 2.7% reporting severe pain that limited their normal activity.

Although research aimed at determining the prototypical pain patient continues (cf. Gamsa, 1994), there is no compelling evidence that shows pain patients as a homogeneous and separate group from individuals without pain (Love & Peck, 1987; Turk & Flor, 1984; Turk & Salovey, 1984). Consequently, in the place of uniformity, many researchers have begun to look for subgroups with different psychological profiles (Armentrout, Moore, Parker, Hewett, & Feltz, 1982; Jensen, Turner, Romano, & Karoly, 1991). Apart from a high frequency of prior physical abuse, sexual abuse, and other trauma, occupational factors play an important role. For instance, overuse of a body part has been shown to lead to specific pain syndromes (Newmark & Hochberg, 1987; Schuldt, Eckholm, Harms-Ringdahl, Aborelius, & Nemeth, 1987).

6.24.3.4 Conversion Disorder

Isolated conversion symptoms are believed to be fairly common and symptoms often disappear after a relatively brief period. In contrast, the diagnosis of conversion disorder is rare and difficult to establish with estimates ranging between 0.001% and 0.3% (APA, 1994). One reason is that symptoms seemingly indicative of conversion disorder are later discovered to be linked to a gradually developing, physical (neurological) disease such as a brain tumor or multiple sclerosis (cf. Fishbain & Goldberg, 1991). Although this condition may occur at any age, onset is typically in late childhood or early adulthood. Onset is often sudden and in response to conflicts or stressful situations such as unresolved grief and sexual trauma. Emotional stress was found to be present before the onset of conversion in 87% of the 53 outpatients in an Indian study by Sharma and Chaturvedi (1995). According to *DSM-IV* (APA, 1994), conversion is five times more common in women than in men and more common in persons of lower socioeconomic status with limited medical or psychological knowledge.

6.24.3.5 Body Dysmorphic Disorder

The prevalence of BDD is largely unknown, but preoccupation with body image and dissatisfaction with some aspect of one's appearance are believed to be widespread in the general population. In fact, according to *DSM-IV* (APA, 1994), BDD may be more common than was previously thought and under-recognized in settings where cosmetic procedures are performed. In terms of a diagnosable condition, Rosen (1995) found that about 1% of a community sample met criteria for BDD with virtually no gender differences in prevalence.

Onset of BDD may be gradual or sudden, and its course is generally continuous and chronic, though fluctuating in intensity. At present, we have only fragmentary and anecdotal reports on etiological factors, and no prospective longitudinal study of BDD has been undertaken (Rosen, 1995). Nevertheless, BDD is thought to start in adolescence when preoccupation with physical appearance is very common. Sociocultural factors influencing people's attitudes towards and dissatisfaction with their bodies seem to play a role in determining the extent to which a real or imagined physical abnormality becomes a cause for concern and preoccupation. Perfectionistic features seem to be related to BDD (Frost, Williams, & Jenter, 1995).

6.24.4 PROBLEMS OF DIFFERENTIAL DIAGNOSIS AND COMORBIDITY

The diagnostic validity of the somatoform disorders has been questioned repeatedly and for good reason. Even the authors of the *DSM-IV* concede that the grouping of these disorders in a single section is based on clinical utility rather than on assumptions regarding shared etiology or mechanisms (APA, 1994). Murphy (1990) indicated that the disorders are not qualitatively distinct but rather merge into each other, making distinctions between individual somatoform disorders hard to define. As an example, pain may occur in any of the somatoform disorders. Ambiguous normative criteria such as "the person's concern is markedly excessive," "grossly in excess of what would be expected," and "slight physical abnormality" create further problems. The distinction between BDD and normal concerns about appearances are as difficult to make as the distinction between BDD and delusional disorder (somatic subtype). The relation and distinction between somatoform disorders and personality disorders have also recently been questioned (Bass & Murphy, 1995; Tyrer, 1995). On the other hand, *DSM* criteria are very selective and will only allow diagnosing patients with a particular symptom profile (Fink, 1996).

In view of all these problems, Fava (1992b) suggests that the concept of abnormal illness behavior should probably replace the somatoform disorders rubric because it provides a more useful conceptual framework for disorders that would otherwise be scattered and unrelated in the *DSM* or that would not find a place at all. Fink (1996) makes a similar point arguing that researchers have been preoccupied with physical symptoms in search for reliable and valid diagnostic criteria for somatization, but have neglected the psychopathology, behavior, and other aspects of the problem. A simplistic reliance upon physical symptoms is questionable for diagnosing somatoform disorders and useless for the purpose of designing treatments. Symptom-focused diagnoses may be artifacts biased by patient suggestibility and a clinician's preoccupation for some disease. Rather than the presence of a specific set of physical symptoms, it is the way a patient interprets, experiences, and responds to a symptom that constitutes psychopathology (Fink). In particular, a somatic attributional style (Robbins & Kirmayer, 1991) may contribute to the translation of personal and social problems into physical symptoms, and prompt patients to present with somatic distress and request somatic treatments.

In sum, the diagnostic validity of somatoform disorders in relation to each other as well as to other clinical syndromes is problematic. The problem even extends to the distinction between the somatoform disorders and general medical conditions. Using a categorical classification system, diagnostic distinctions cannot be made to a satisfactory degree. What is needed is a multidimensional classification system incorporating psychological, somatic, and social dimensions (cf. Mayou, Bass, & Sharpe, 1995). Nonetheless, in the present diagnostic criteria the origin of somatic complaints assumes an important role for differential diagnosis. *DSM-IV* distinguishes symptoms as part of a "real disease" (general medical condition) from symptoms that are under a patient's voluntary control or intentionally produced. We will therefore briefly discuss attempts to distinguish somatoform disorders from each other and from a general medical condition. The interesting relation between somatoform and anxiety disorders will then be discussed to show how a classification system that focuses on the functions of maladaptive health-related behaviors, and defines problems in a dimensional rather than categorical manner, may be more beneficial for clinicians, researchers, and patients alike. Such an approach avoids the pitfalls of putting people into distinct categories and provides information that is directly useful for the design of clinical interventions.

6.24.4.1 Somatoform Disorders vs. General Medical Conditions

The presence of a general medical condition that could account for the presenting symptoms must be carefully examined and considered in every case where physical problems are the focus of a patient's complaints. Symptoms such as pain or fatigue may be related to a wide array of problems ranging from normal sensations to fatal diseases. Health professionals are very much aware of the danger of misdiagnosing a somatoform disorder and of missing the presence of actual physical problems—particularly diseases with a slow or diffuse onset such as multiple sclerosis, brain tumors, or systemic lupus. Some patients diagnosed with somatoform disorders or "functional problems" are ultimately diagnosed with a demonstrable medical condition and must be regarded as initial false-positives (for a particularly poignant example, see Fishbain & Goldberg, 1991). On the other hand, advances in medical diagnostic procedures (e.g., PET and magnetic resonance imaging (MRI) scans) have resulted in more accurate diagnostic decisions and reduced the number of false-positive diagnoses of somatization disorder (Kent, Tomasson, & Coryell, 1995).

Any diagnosis of somatoform disorders should be made with caution and only after careful physical examination. This recommendation is also supported by the fact that it is occasionally difficult for physicians and psychologists alike to determine the "true" nature of somatic complaints. In a study of 200 successive patients undergoing cardiac catheterization, it was found that neither standard medical tests before catheterization nor standard psychological questionnaires alone were able to discriminate reliably chest pain patients with coronary artery disease from patients without heart disease. Diagnostic accuracy only improved when cardiac catheterization was considered along with results from psychological assessments (Eifert, Edwards, Thompson, Haddad, & Frazer, 1997).

In addition, there is at times a reciprocal relationship between health anxiety and somatic symptoms. For instance, Salkovskis (1996) describes how the very safety-seeking behaviors designed to reduce anxiety frequently increase the symptoms that are the focus of anxiety. He cites the example of patients who palpate or rub lumps until they swell and cause pain. Several authors also point to potential pathophysiological mechanisms that may underlie unexplained physical symptoms. Sharpe and Bass (1992) describe various pathophysiological mechanisms in abdominal pain, chest pain, chronic fatigue, breathlessness, and irritable bowel syndrome that can be detected by routine or advanced medical evaluation. For instance, symptoms can be due to excessive physiological activity (e.g., smooth-muscle contraction, striated-muscle contraction, changes in endocrine secretion and in blood flow) that may be accentuated by stress and intense emotions. Both in fairness to the patient, and to design the most appropriate intervention, we should be careful in the use of such terms as unexplained physical symptoms and functional defects. Terms such as "nonorganic ..." should be avoided completely.

6.24.4.2 Differentiating Somatoform Disorders

Differentiating the various somatoform disorders using *DSM-IV* criteria is difficult because criteria are vague and there is considerable overlap of symptoms, Nonetheless, several distinctions can be made and are briefly discussed below.

6.24.4.2.1 Somatization disorder vs. hypochondriasis

In somatization disorder the patient's attention is directed at the somatic symptoms themselves, whereas in hypochondriasis symptoms are generally less elaborate and the patient is concerned about a possible underlying illness (Murphy, 1990). As a result, hypochondriacal patients experience higher levels of anxiety, whereas patients with somatization disorder experience lower levels of anxiety or no anxiety at all.

6.24.4.2.2 Somatization disorder vs. pain disorder

Although pain symptoms are included in the diagnostic criteria for somatization disorder, symptoms other than pain must be present before a diagnosis can be assigned. In contrast, pain is the predominant (and frequently exclusive) focus of the clinical presentation of a person with pain disorder.

6.24.4.2.3 Somatization disorder vs. conversion disorder

A key difference is the sheer number of symptoms. A person with somatization disorder, by definition, must report at least eight symptoms of four different types, whereas a person with conversion disorder typically manifests only one symptom.

6.24.4.2.4 Hypochondriasis vs. body dysmorphic disorder

Although hypochondriasis and BDD share some features (e.g., bodily preoccupation, repetitious body checking, reassurance seeking, and medical consultations), individuals engage in these behaviors for different reasons. Persons with hypochondriasis are afraid of serious illness, whereas persons with BDD are concerned about the physical appearance of their body.

6.24.4.3 Relation Between Somatoform Disorders and Depression

There is a high comorbidity of all somatoform disorders with depression and to a lesser extent with dysthymic disorder. For instance, in a prospective study of 30 psychosomatic clinic inpatients, Rief, Hiller, Geissner, and Fichter (1995) found high lifetime comorbidity between various somatoform disorders and both depression (86%) and anxiety (43%). Remission rates were higher when somatoform disorders were not accompanied by other psychiatric disorders (e.g., anxiety, depression, or addiction) than in cases with comorbidity. In addition, the presence of somatoform disorders increased the risk for other psychiatric conditions (Rief et al.). Several studies found a striking relation between pain and major depression or dysthymic disorder but the specifics of that relation remain elusive (Chaturvedi & Michael, 1986; France, Krishnan, Houpt, & Maltbie, 1984; Turk, Okifuji, & Scharff, 1995).

6.24.4.4 From Differential Diagnosis to Dimensional Classification

Despite considerable degree of overlap in the symptoms of persons with hypochondriasis, disease phobia, and panic disorder, also reflected in reports of high comorbidity rates (Warwick & Salkovskis, 1990), our understanding of the relation between somatoform and anxiety disorders is poor (Barlow, 1988; Forsyth & Eifert, 1998). In the following discussion, we will adopt a dimensional approach to understanding illness-related concerns that might be useful for both assessment and treatment purposes. Delineating points of overlap and differences is also an important first step toward designing more thorough empirical investigations of the subject.

6.24.4.4.1 Hypochondriasis and disease fear: a dimensional perspective

According to Pilowsky's (1967) classic study, hypochondriasis has three dimensions: disease phobia, disease conviction, and bodily preoccupation. These dimensions are still the basis for the current *DSM* criteria for hypochondriasis. Unfortunately, the *DSM* definition fails to distinguish hypochondriasis as a fear of disease from a conviction of having a disease. This failure could, at least in part, account for the ambiguity in the use of the diagnostic label of hypochondriasis (cf. Eifert, 1992). Fear of having a physical disease has quite different theoretical, diagnostic, and therapeutic implications from a conviction of being seriously ill, regardless of whether the conviction is accompanied by fear or not.

A clear separation of the different dimensions of hypochondriasis may contribute to a better understanding of such problems and result in more appropriate treatments. We view hypochondriasis as a syndrome where persons present with problems that fall on a continuum along four dimensions.

(i) *Preoccupation with the body and its functioning*. Excessive awareness of and interest in bodily sensations and functioning, with or without physical complaints, constitutes what Starcevic (1988) aptly called "the hypochondriacal core." Such bodily preoccupation, especially when coupled with somatic complaints, may produce a state of somatic uncertainty and form the basis for the other three dimensions of the disorder.

(ii) *Disease suspicion or conviction*. The person has the suspicion or is convinced of having a serious physical disease; suspicion and conviction are on a continuum of strength, and in rare cases the conviction may reach delusional intensity.

(iii) *Disease fear*. The person fears having a serious physical disease.

(iv) *Safety-seeking behaviors*. The function of behavior such as repeated requests for medical examinations and tests, bodily checking, verbal complaints, and seeking reassurance is to reduce worry and anxiety over physical illness (Eifert, 1992; Salkovskis, 1996; Warwick & Salkovskis, 1990).

Although a person could score highly on any one or all four dimensions, bodily preoccupation and disease suspicion/conviction are most central to hypochondriasis. As indicated, disease suspicion/conviction may or may not be accompanied by fear of the suspected disease. Clinically, this feature is most apparent in patient's resistance to medical reassurance. For instance, Fava and Grandi (1991) indicated that patients may continue to be extremely worried about their health even though their fear of suffering from a specific disease may be eliminated by a satisfactory medical examination. In other words, a patient's morbid preoccupation with disease may continue in the absence of any specific disease phobia maintaining and prolonging a person's suffering and keeping them from consulting a psychologist.

Disease phobia is a persistent unfounded fear of suffering from or contracting a disease (Bianchi, 1973, Eifert, 1992) and may occur in the absence of a conviction or suspicion of having a disease. For example, a person may be afraid of having a heart attack or contracting cancer without being convinced or suspicious of having heart disease or cancer. According to

Fava and Grandi (1991), there are two main clinical characteristics of disease phobia that distinguish it from more general hypochondriasis. One feature is the specificity and temporal stability of symptoms. For instance, it was found that most cardiophobic patients were only afraid of having a heart disease but not of other diseases (Eifert et al., 1996). Even over time, these patients are unlikely to develop fears focused on other organ systems. This specificity led Marks (1987) to view disease phobias as a subtype of hypochondriasis focused on a specific illness. The second feature of disease fears is that they manifest themselves in cue-controlled attacks of shorter durations. For example, a cardiophobic person's fear of having a heart attack becomes salient and particularly strong only in response to the acute experience of chest pain and heart palpitations (Eifert 1992; Eifert et al. 1996). This feature of disease phobias is in contrast to the morbid preoccupations of persons with primary hypochondriasis who constantly worry and ruminate about their health.

6.24.4.4.2 Relation between hypochondriasis and anxiety disorders

A discussion of the dimensions of excessive health anxiety raises several questions regarding the relation of this type of anxiety to other anxiety-related problems, which will be discussed next.

(i) Comorbidity of disease phobias and hypochondriasis with panic disorder

Warwick and Salkovskis (1990) report that 59% of hypochondriacal patients seen in their clinic also met *DSM-III-R* criteria for panic disorder. Other studies (Beitman et al., 1987; Eifert et al., 1996) found that between 25% and 50% of cardiology persons with heart-focused anxiety also suffer from panic disorder. Panic patients with agoraphobia have been shown to score as high as hypochondriacal patients in areas such as somatic preoccupation, disease phobia, and illness conviction (Noyes, Reich, Clancy, & O'Gorman, 1986). Following treatment, significant reductions in hypochondriasis scores occurred in those panic patients who improved with treatment. Fava, Kellner, Zielezny, and Gurand (1988) also found that before treatment, patients with panic disorder and agoraphobia scored significantly higher on several illness fear and behavior measures than a group of healthy controls. Following the successful treatment of panic, however, these group differences had disappeared.

(ii) Modulation and timing of anxiety

Fava and Grandi (1991) describe the relation of disease phobia to hypochondriasis as similar to that of panic disorder to generalized anxiety. This perspective is based on a difference in the modulation and timing of anxiety in disease phobia and panic compared to hypochondriasis and generalized anxiety disorder. As in panic disorder, which is characterized by a sudden surge of aversive sensations and fear that tends to subside within 30–45 minutes, persons with disease phobias tend to experience anxiety attacks of a relatively short duration when exposed to feared cues. In contrast, persons with primary hypochondriasis experience more constant and chronic levels of worry about body sensations and illness, similar to the chronic levels of worry found in generalized anxiety disorder—although in both disorders worries and fears may occasionally escalate into a "crescendo of panic" (Salkovskis & Clarke, 1993; Warwick & Salkovskis, 1990). In addition, these authors point out that persons with hypochondriasis typically judge the danger they fear to occur at some distant time in the future, whereas panic patients fear an imminent catastrophe.

(iii) Misinterpreted symptoms and focus of fear

In panic disorder as well as disease phobia, individuals misinterpret autonomic symptoms that are involved in acute anxiety attacks. Persons with disease fears, however, tend to report fewer and less severe panic symptoms (Beck, Berisford, Taegtmeyer, & Bennett, 1990) and their fear is more specific and focused on one organ or organ system (Eifert, 1992; Eifert et al., 1996). Such individuals do not fear the symptoms themselves but what they seem to indicate (i.e., serious disease). On the other hand, persons with panic disorder tend to fear generalized uncontrollable aversive autonomic body sensations, that is, they fear the actual bodily sensations (see Chambless & Graceley, 1989). They also have fewer and less pronounced illness behaviors and beliefs than persons with either disease phobias or hypochondriasis (Eifert, Seville, Antony, Brown, & Barlow, 1992). Hypochondriacal patients are more likely to misinterpret symptoms which are not subject to direct amplification such as lumps, skin rashes, and blemishes (Salkovskis & Clark, 1993), and their fear is focused on these health/disease issues.

(iv) Behavioral avoidance

Individuals with disease phobia typically cannot avoid the stimuli they fear (pain and palpitations) and therefore attempt to avoid activities which they believe bring on the dreaded physical symptoms (Eifert et al., 1996). They may also engage in a number of behaviors that are designed to protect their body or a specific organ that they are afraid of damaging. Warwick and Salkovskis (1990) have identified another important difference between hypochondriacal and panic patients in patterns of escape and avoidance related to illness. Hypochondriacal patients have more time to prevent the anticipated disaster by seeking medical attention because the anticipated harm is perceived as much less imminent. In contrast, panic patients are likely to be overwhelmed by the sudden surge of arousal and fear during a panic attack and perceive leaving the situation and their future avoidance as their only option (Salkovskis, 1996).

In conclusion, we believe that a dimensional classification system could help overcome the pitfalls of pigeon-holing individuals into existing diagnostic categories. Identifying dimensions that allow a classification of illness behavior based on the function that such behavior serves, rather than its topography, might lead to a better understanding and improved treatments of persons with somatoform problems. Apart from the number and type of physical complaints, some of these dimensions include the presence and extent of preoccupation with body and health, symptom misinterpretation, disease suspicion or conviction, disease fear, safety-seeking approach and avoidance behavior, focus and modulation of worry and fear, and pathophysiological processes. Barlow (1988) noted that classification of any disorder, whether dimensional or categorical, should reliably describe subgroups of symptoms or behaviors that are readily identifiable by independent observers on the basis of operational definitions. There should also be some clinical usefulness or value in identifying these subgroups or dimensions such as predicting specific response to treatment, course of the disorder, and tailoring treatment (Eifert, 1996; Eifert, Evans, & McKendrick, 1990). We hope that a dimensional analysis of somatoform disorders will move us closer toward reaching that goal.

6.24.5 CONTEMPORARY THEORETICAL PERSPECTIVES

Although some theoretical models have been advanced in relation to the process of somatization (cf. Kellner, 1991), somatoform disorders are understudied and poorly understood (Barlow, 1988; Hitchcock & Mathews, 1992). As cognitive-behavioral concepts predominate contemporary perspectives on somatoform disorders, we will briefly discuss some of these concepts. In terms of specific disorders, we will concentrate on hypochondriasis and pain since much of recent research has focused on these problems.

6.24.5.1 Dysfunctional Processes in the Somatoform Disorders

6.24.5.1.1 Abnormal illness behavior

Pilowsky (1993, p. 62) defined abnormal illness behavior as the "persistence of a maladaptive mode of experiencing, perceiving, evaluating, and responding to one's own health status, despite the fact that a doctor has provided a lucid and accurate appraisal of the situation and management to be followed (if any), with opportunities for discussion, negotiation and clarification, based on adequate assessment of all relevant biological, psychological, social and cultural factors."

Abnormal illness behavior is not a diagnosis as such, but refers to the disagreement between the doctor and patient about the sick role to which the patient feels entitled (Pilowsky, 1993). Sharpe, Mayou, and Bass (1995) argued that the concept of abnormal illness behavior is not only valuable for understanding patients with functional somatic symptoms but for understanding the behavioral aspects of all illness.

6.24.5.1.2 Perception and attention

Cognitive processing of medical information as well as attention to and attribution of symptoms are believed to be central features in all somatoform disorders. Pennebaker (1982) conducted various studies on the role of attention in symptom perception and concluded that the more salient a somatic symptom (and the lower the amount of external distraction), the more likely and more intense the original symptom is perceived. An implication of this finding is that deficient external stimulation may pave the way for an increased attention to somatic symptoms Pennebaker also demonstrated that simply directing a person's attention to bodily sensations increases reports of symptoms. Selective attention to internal stimuli could thus augment somatic concerns.

Although attentional bias has been well documented in individuals with anxiety disorders showing that attention is biased towards threat-related stimuli (cf. MacLeod & Mathews, 1991), empirical evidence for this type of bias in somatoform disorders is mixed. Most studies have examined hypochondriacal patients

(Barsky et al., 1995; Tyrer, Lee, & Alexander, 1980) or normal subjects with high scores on a hypochondriasis scale (Hanback & Revelle, 1978; Hitchcock & Mathews, 1992). In a series of experiments, Hitchcock and Mathews were able to demonstrate enhanced registration and availability of illness information. They also found that hypochondriacal subjects interpreted ambiguous information as threatening, although this bias was applied equally to illness and social ambiguity. By contrast, subjects did not show a bias for making rapid automatic inferences about bodily sensations implying illness. Hitchcock and Mathews rightly caution, however, that it is unclear whether enhanced perceptual sensitivity to illness cues is a cause or consequence of hypochondriacal anxiety.

A particular perceptual disturbance in body image has been demonstrated in persons with BDD although the specific processes involved have not been studied in detail. Rosen (1995) proposed an integrative formulation of BDD linking processes such as thinking about the presumed abnormality in appearance with behavioral features such as avoidance of social situations, camouflaging, checking, and undertaking beauty remedies. Preoccupation with the imagined defect is especially salient in social situations and may take on delusional or obsessional qualities.

6.24.5.1.3 Deficits in emotion processing (alexithymia)

Alexithymia literally means “no words for feelings.” The concept refers to a hypothesized communicative function of somatic symptoms. Its key features are a relative constriction of emotional functioning, poverty of fantasy life, and inability to find appropriate words to describe one’s emotions (Taylor, Bagby, & Parker, 1991). Alexithymic individuals seem to be vulnerable to mounting tension from undifferentiated states of unpleasant emotional arousal. This vulnerability is presumably caused by a disturbance in the processing of emotional awareness that is believed to interfere with the subject’s ability to experience and express emotions. For example, in a sample of normal volunteers, Vingerhoets, Van Heck, Grim, and Bermond (1995) found strong negative correlations between alexithymia and the expression of emotions, daydreams, and fantasies, and planful and rational actions. Bach and Bach (1995) found high alexithymia scores to be predictive of persistent somatization. More recently, the concept of alexithymia has also been discussed in relation to a variety of psychological traumata (Salminen, Saarijävi, & Äärelä, 1995).

6.24.5.2 Disorder-specific Theoretical Models

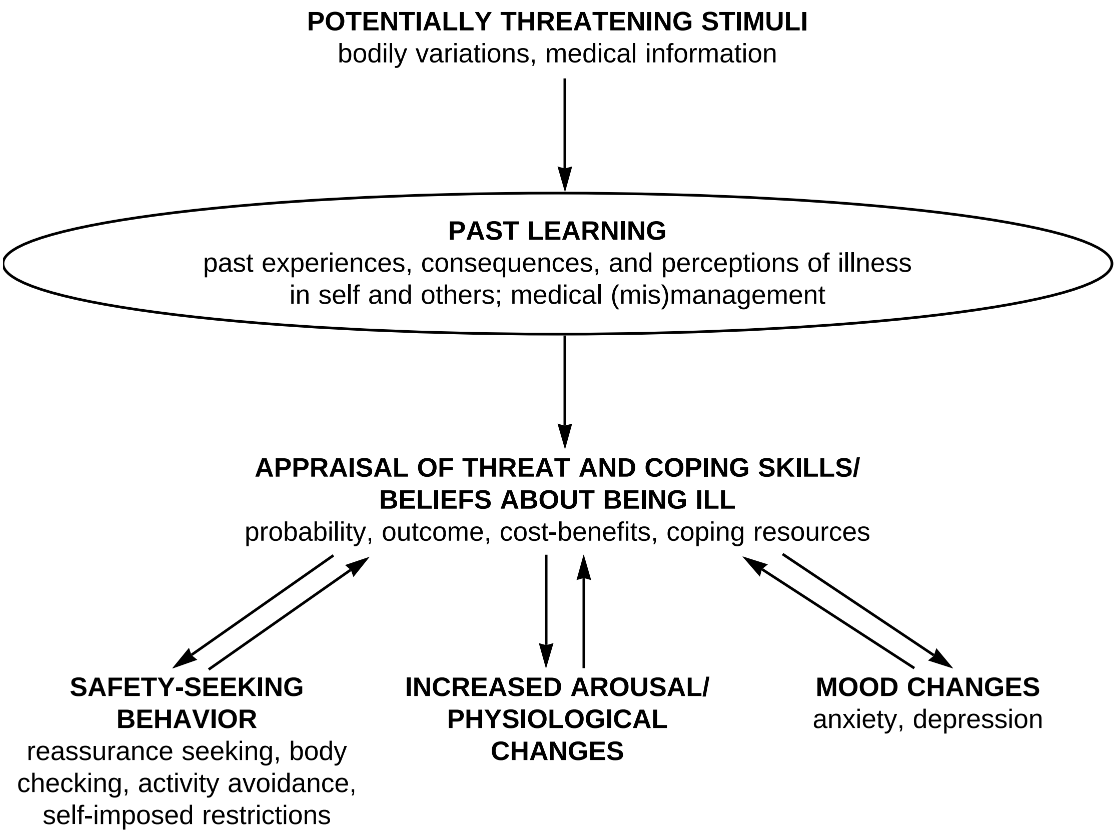
As indicated, cognitive-behavioral perspectives and research have been helpful in providing a fledgling basis for a better understanding and treatment of persons with somatic problems. Below we will focus on cognitive-behavioral perspectives of hypochondriasis and pain as most recent research has dealt with these problems.

6.24.5.2.1 Hypochondriasis

Behavioral theories of excessive health anxiety stipulate that internal cues which have been associated with threat and bodily harm (unconditioned stimuli) can serve as conditioned stimuli (Forsyth, Eifert, & Thompson, 1996; Miller, 1977). In the presence of these stimuli, individuals will begin to exhibit conditioned responses such as anxious behavior and physiological changes. Classically conditioned instances of hypochondriacal behavior can be maintained through operant reinforcement. Somatic complaints may lead to attention, sympathy, and escape from or avoidance of undesirable tasks or situations. Such consequences may reinforce symptom reporting and other hypochondriacal behavior (Kellner, 1985). If somatic complaints are ignored in the patient’s home, hypochondriacal behavior in the presence of family and friends may be extinguished, but it may also lead the patient to increase medical assistance-seeking in the hope of receiving attention from a physician instead.

These are examples of contingency-shaped behavior, but observers may also learn to exhibit hypochondriacal behaviors through the process of modeling (Craig, 1986) or rule-governed behavior (Hayes & Wilson, 1994). According to Kellner (1985), hypochondriacal behavior worsens as the conditioning process repeats.

As can be seen in Figure 1, cognitive theories of health anxiety emphasize the role of misinterpretations of innocuous bodily changes or of information provided by doctors, friends, or the media. Patients focus on essentially harmless physical sensations, which they consistently misrepresent and misinterpret as indications of physical illness (Barsky & Klerman, 1983; Warwick & Salkovskis, 1990). As a result, symptoms and medical information tend to be perceived as more dangerous than they really are and a particular illness is believed to be more probable than it really is (Salkovskis, 1996). According to Salkovskis, the onset and maintenance of health anxiety involves the complex interaction of several factors. Previous experiences and perception of illness in self and



POTENTIALLY THREATENING STIMULI
bodily variations, medical information
PAST LEARNING
past experiences, consequences, and perceptions of illness in self and others; medical (mis)management
APPRAISAL OF THREAT AND COPING SKILLS/ BELIEFS ABOUT BEING ILL
probability, outcome, cost-benefits, coping resources
SAFETY-SEEKING BEHAVIOR
reassurance seeking, body checking, activity avoidance, self-imposed restrictions
INCREASED AROUSAL/ PHYSIOLOGICAL CHANGES
MOOD CHANGES
anxiety, depression

Figure 1 Cognitive-behavioral model of maladaptive illness-related behavior (adapted from Warwick & Salkovskis, 1990, and Salkovskis, 1996; cf. Eifert, 1992).

others ('whenever I had physical symptoms as a child I was taken to the doctor") are often the root of future hypochondriacal behavior and may result in the formation of dysfunctional beliefs ('bodily symptoms are always a sign that something is wrong"). As a result, harmless incidents or physical symptoms activate these negative assumptions and other catastrophic thoughts ('this is going to get worse"), which in turn lead to behavior changes such as increased safety-seeking and avoidance as well as heightened physiological arousal, anxiety, and depression. Repeated cycles of this kind may lead to an exacerbation of hypochondriacal symptoms and perceptions of oneself as a sick and incapable individual (Salkovskis, 1996).

6.24.5.2.2 Pain

According to the behavioral theory of pain developed by Fordyce (1976), pain behavior is often acquired through respondent conditioning ("sensory pain") and maintained through operant conditioning ("psychological pain"). Initially, pain is considered to be an overt reflexive response to an antecedent noxious stimulus such as an injury. Following onset, future pain behavior is subject to selection by consequences. Verbal reports and nonverbal expressions of pain are maintained because of the associated delivery of positive and negative reinforcers. As indicated, pain behavior may be positively reinforced through tangible benefits, attention, or stimulation (i.e., concern or sympathy). Pain behavior may also be negatively reinforced when it results in the avoidance of or escape from undesirable activities or stimulation such as work or unwanted sexual encounters. In the absence of direct exposure to the environmental contingencies, these behaviors may be acquired or taught through modeling (Craig, 1986). Respondent and operant conditioning may interact in the onset and maintenance of pain behavior (Rachlin, 1985). For instance, the avoidance of physical activity can lead to muscle fibers shortening and losing elasticity. This can be quite painful and, as a consequence, persons tend to avoid or escape from physical activity. Such avoidance and escape are negatively reinforced when they lead to a short-term decrease of pain, but avoidance and escape may also result in long-term cost by exacerbating the physical condition of the individual and lead to a vicious circle (Flor et al., 1990). A number of studies have shown that pain behavior is susceptible to social reinforcement. For example, Cairns and Pasino (1977) reported that exercise behavior increased when praise was delivered contingently and decreased soon after praise delivery was discontinued. Moreover, pain patients who perceived their wives as solicitous exhibited more pain behavior in the presence of their wives than patients who perceived their wives as nonsolicitous (Flor, Kerns, & Turk, 1987).

Although pain is a subjective phenomenon and difficult to quantify, behavioral researchers have attempted to quantify pain behavior. In a choice situation, the relative frequency of responding (either the number of responses or the amount of time responding) allocated to a particular alternative closely approximates the relative frequency of obtained reinforcement for that alternative. This relation is called the matching law (Baum, 1974; Herrnstein, 1970). Applied to pain, the matching law suggests that the frequency of an individual's adaptive behavior (e.g., pain coping without complaining), compared to maladaptive pain behavior (e.g., verbal complaints, facial contortions), will match the relative frequency of reinforcement obtained for each type of behavior. In other words, if maladaptive pain behavior is reinforced more than adaptive behavior, the likelihood of future maladaptive behavior will increase, whereas adaptive pain coping behavior becomes less likely. Conversely, if a patient's maladaptive behavior is reinforced less than adaptive pain behavior, preference will shift to adaptive pain behavior. The matching law is clinically useful because it allows us to quantify how much reinforcement will be necessary to sustain a particular level of a given behavior. Fernandez and McDowell (1995) found the matching law to provide accurate descriptions of pain behavior. Although there are no other studies applying the matching law to pain, the clinical utility of the matching law has been demonstrated in the study of self-injurious behavior (McDowell, 1981, 1982), social behavior (Conger & Killeen, 1974), and disruptive behavior of mentally retarded children (Martens & Houk, 1989). The matching law could provide a promising, more objective approach to quantifying pain behavior.

Cognitive-behavioral perspectives emphasize that maladaptive pain behavior is due to negative or unrealistically high expectations about experiencing pain as well as low levels of perceived competence to deal with pain (Schermelleh-Engel, Eifert, Moosbrugger, & Frank, 1997). Apart from the physical characteristics of the pain stimulus, or the amount of tissue damage, differences in coping style are particularly important for the perception of pain and associated mood states (Turk et al., 1995). Our own research specifically supports the importance of perceived competence for coping with chronic pain, indicating that perceived competence determines how intense persons experience pain, how much they are disturbed by it, and whether they engage in adaptive or maladaptive coping behavior (Schermelleh-Engel et al.). Although the coping process is not systematically affected by the characteristics of the pain stimulus, a person's type of coping behavior affects the impact of the pain stimulus (cf. Asmundson & Norton, 1995). Using path analytic structural equation modeling, we found that coping behavior is directly influenced by a person's perceived level of competence and only indirectly affected by pain intensity and pain-related anxiety and depression. Decreasing competence appears to lead to increasing pain intensity and increasing pain emotions, which, in turn, increase maladaptive behavior. Conversely, individuals who trust in their abilities to cope adequately with pain are more likely to engage in adaptive behavior, irrespective of how anxious they are; such persons also do not suffer as much as individuals with low perceived competence.

6.24.5.3 Future Challenge: Integrative Biobehavioral Theories

Throughout this chapter we have alluded to the significant degree of overlap between somatization, hypochondriasis, and pain. Comprehensive theoretical accounts are just beginning to emerge for these problems, but they are impeded by a relative lack of agreement on what precisely somatization refers to. For instance, do persons diagnosed with "unexplained physical symptoms" (e.g., Speckens et al., 1996) suffer from somatization disorder, hypochondriasis, or are they a mix between the two? Moreover, presenting with unexplained physical symptoms does not imply that there is no medical or other explanation for the symptoms. In some (although certainly not all) cases, an explanation might be found if more sophisticated tests such as MRI or PET scans were conducted. Moreover, there is a significant "gray area" that medical colleagues often refer to when they speak of persons who do have some degree of demonstrable pathophysiology. Yet patient symptom reports, or their response to symptoms, seem to be "exaggerated" in view of the degree of actual tissue damage or other physical changes. Since neither physicians nor psychologists can adequately pinpoint or understand the symptoms and behavior of such patients from their respective perspective alone, these patients should be approached from a multidisciplinary perspective. Unfortunately, theories that attempt to integrate biological/medical with psychological knowledge are rare. A notable exception is the psychobiological account of chronic pain, which we will briefly summarize as an example of what more adequate theories for persons with somatic problems might look like in the future.

The early physiological views of pain regarded pain simply as a sensation resulting from patterns of stimulation from free nerve endings; pain intensity was believed to be directly proportional to the amount of peripheral nociceptive input related to tissue damage (Dallenbach, 1939). Proposed by Melzack and Wall (1965), the gate control theory (GCT) was one of the first psychophysiological theories to challenge this assertion. According to the GCT, pain is due to the complex interplay of receptors, afferent and efferent processes, and spinal and supraspinal processes. More recent theories (cf. Cailliet, 1993) have expanded the basic concepts of the GCT to relate current information on physiological processes (e.g., the role of acid metabolites and opiate receptors) to psychological factors. An integrative psychobiological theory of chronic pain proposed by Flor et al. (1990) relates concepts and findings from areas such operant, respondent, observational, and cognitive learning and relates them to biological concepts and physiological findings.

Flor et al. (1990) propose that pain is a complex response that comprises subjective-psychological, motor-behavioral, and physiological-organic components. Stress may precipitate and facilitate a particular pain disorder to which the individual is already predisposed on an unlearned or learned basis. The learned aspect of this predisposition consists of a reduced threshold for nociceptive activation due to previous trauma or social learning experiences resulting in a physiological response stereotypy of a specific body system or group of muscles. Stress and pain episodes may trigger a host of autonomic and muscular reactions, particularly sympathetic activation and elevated muscle tension levels. If stress or pain-related muscular contractions occur repeatedly, a number of muscular and sympathetic reflexes lead to increases in muscle tension and to sympathetically mediated vasoconstriction. If the muscular contractions are of sufficient intensity, frequency, and duration, there will not be sufficient blood and oxygen in the affected muscles and algogenic (pain-inducing) substances will be released. The ensuing pain experience increases muscular and sympathetic hyperactivity and may thus lead to a vicious circle. As these processes also increase the sensitivity of chemo-nociceptors, the likelihood of future pain also increases. This feedback circle, in particular, nicely illustrates the interplay between physiological and psychological processes and helps us understand how both physiological changes and the person's response to such changes may interact to create the problems that persons with chronic pain struggle with.

6.24.6 TREATMENT OF SOMATOFORM DISORDERS

Psychologically distressed medical patients who present with unexplained somatic symptoms are high users of care and their doctors regard them as frustrating and difficult to treat (Mayou & Sharpe, 1995). There is often a mismatch between the expectations of these patients and their doctors' abilities and communication skills. For instance, Eifert (1992) pointed out that diagnoses such as functional heart problem, nervous heart, atypical chest pain, and pseudoangina can be easily misinterpreted by a cardiophobic patient who is determined to believe that some significant cardiac disease is being described. As a result, healthcare providers often feel frustrated and emotionally drained because these patients are obviously in need of psychological support but resent being referred to a psychologist or psychiatrist. Owing to the overlapping psychological processes involved in the various somatoform disorders, we will first outline treatment recommendations that are applicable to most individuals with any of the somatoform disorders. This discussion will be followed by some specific recommendations and outcome data for individual disorders.

Patients often perceive the use of diagnostic labels such as hypochondriasis as an insult because these labels are seen to imply that patient problems are not real and are "just in their head." Accepting and understanding the symptoms rather than refuting or arguing with the patient is therefore the most important condition for engaging the patient in a therapeutic working relationship (cf. Bass & Benjamin, 1993). In the engagement stage of treatment, patients are helped to see that there may be an alternative explanation for the difficulties they are experiencing (Salkovskis, 1996). For instance, although chest pain can be due to coronary artery disease, it can also be caused by hyperventilation-induced chest wall muscle tension (Eifert, 1992). The general treatment strategy is to test such alternative nonmedical or benign medical explanations for symptoms and to conduct therapy in the context of an experiment that provides an opportunity for testing alternative hypotheses (Salkovskis, 1996).

Rather than merely telling patients there is no "organic" reason for their chest pain, an explanation of symptoms that overcomes the nonorganic–organic dualism provides the patient with a more acceptable rationale and reassurance. For instance, to provide a patient with a credible explanation of how anxiety and chest wall muscle tension can result in chest pain, patients may be given a chest-focused relaxation with EMG feedback that literally shows them how they can change their chest tension levels (Eifert, 1996). Salkovskis and Warwick (1986) found that reassurance which only informs the patients that there is nothing organically wrong with their body will actually increase future reassurance-seeking rather than decrease it. On the other hand, appropriate reassurance and feedback that provides the patient with new and alternative explanations is the key to successful treatment, and in some cases, may help prevent the development of chronic somatization problems in the first place. It is therefore important that medical professionals are trained to deal with patients in this manner. For example, Goldberg, Gask, and O'Dowd (1989) developed a training program for primary care physicians that included making patients feel understood by carefully listening to their complaints and symptoms, changing the agenda of the actions to be undertaken from a somato-medical focus on bodily symptoms to a psychological perspective focusing on emotional distress. Physicians were also taught how to help patients reattribute bodily symptoms by linking them to psychological factors.

Another important treatment strategy is withholding unnecessary medication and medical examinations (response prevention for safety-seeking behaviors). A symptom diary is used to get a prospective, rather than retrospective, view of the symptoms' course, intensity, and relation to life stresses. Rief (1996) suggests starting off with a symptom-oriented treatment and, in the second phase of therapy, shifting towards more general goals, such as occupational problem-solving, social skills training, and quality of life enhancement.

6.24.6.1 Somatization Disorder

Most articles refer to the management rather than to the treatment of patients with persistent somatic problems (e.g., Bass & Benjamin, 1993). Early diagnosis and the prevention of unnecessary medical and surgical investigation are deemed to be of primary importance. Most somatization patients have distinct expectations regarding treatment goals and procedures and try to persuade their doctors to follow their wishes for further medical investigations and treatments. Bass and Murphy (1990) state that treatment often involves long-term supportive psychotherapy and must be directed toward controlling the demands on medical care as well as the treatment of symptoms and social disability. These authors recommend the following five steps: (i) establish a diagnosis by collecting appropriate medical and psychosocial information; (ii) encourage a long-term supportive relationship with only one understanding primary care physician to prevent doctor-shopping and to coordinate all actions; (iii) see patients on regular appointments rather than on demand to prevent reinforcement of illness behavior; (iv) regard the patient's physical complaints as a form of communication rather than as evidence of disease; and (v) minimize the use of psychotropic drugs and/or analgesic medication. In general, adaptive behavior is encouraged and promoted, whereas sick role behavior is ignored as much as possible. A study by Smith, Monson, and Ray (1986) found that such a treatment program did not lead to improvements on any of the measures of mental, physical, or social health, but patient healthcare was less costly. In contrast, Krasner, Rost, Cohen, Anderson, and Smith (1995) demonstrated that eight sessions of brief group therapy improved physical and mental health at one year follow-up. Treatment focused on coping with the nature and consequences of the physical symptoms, general problem-solving, and helping patients take more control of their lives.

A randomized controlled trial examining a comprehensive cognitive-behavioral approach for medically unexplained physical symptoms was conducted by Speckens et al. (1996). This team compared a cognitive-behavioral intervention group of 39 general medical outpatients with a control group of 40 patients receiving optimized medical care. The 6–16 sessions of cognitive-behavioral therapy included (i) imaginary exposure and distraction techniques to break the vicious circles of cognitive avoidance and preoccupation; (ii) activity scheduling, exposure *in vivo*, and response prevention to decrease avoidance behavior; (iii) relaxation training, breathing exercises, and physical exercises; and (iv) problem-solving or social skills training to overcome any problems in interpersonal relationships. At both 6 and 12 month follow-ups, compared to the control group, the intervention group reported lower intensity and frequency of symptoms, reduced illness behavior, less sleep impairment, and fewer limitations in social and leisure activities.

6.24.6.2 Hypochondriasis

Traditionally, individuals with hypochondriasis were considered difficult to treat and their prognosis was regarded as poor. For instance, early studies assessing the effectiveness of a variety of psychological interventions available at that time (e.g., Kenyon, 1964) found 40% of patients with primary hypochondriasis to be unchanged or worse following treatment. Although patients with unexplained physical symptoms and/or health anxiety still pose a considerable challenge for therapists, cognitive-behavioral interventions have yielded encouraging results.

The first comprehensive cognitive-behavioral treatment formulations were provided by Warwick and Salkovskis (1990). Patients are instructed to self-monitor during hypochondriacal episodes, paying careful attention to environmental events, physical symptoms, associated cognitions, and their resulting hypochondriacal behavior. As indicated, their treatment is directed at evaluating alternative, nonthreatening explanations of body-related observations that patients misinterpret as signs of serious disease. Two possible explanations for the patient's problem are considered alongside each other rather than as mutually exclusive alternatives (Salkovskis, 1996). Patients are then asked to engage in a variety of behavioral experiments to test these new explanations and therapy proceeds as an evaluation of the relative merits of the alternative views. Salkovskis emphasizes that inappropriate safety-seeking prevents individuals from discovering that their fears are groundless. Hence, the key function of exposure exercises and response prevention is to allow patients to repeatedly experience feared bodily sensations to disconfirm fears. Thereby patients learn that the things they are afraid of do not actually happen or that consequences are not as bad as they expected.

A system of differential reinforcement may need to be added for individuals who gain sympathy or interest for physical complaints but may receive little attention otherwise. In those cases, family members and other individuals the patient has contact with (including the therapist) should reinforce patient initiation of conversation on any topic other than symptoms (healthy conversation). This reinforcement could consist of praise or increased attention. As the patient engages in more healthy conversation, the natural contingencies (e.g., reduced medical bills, more pleasant interactions with others) should begin to maintain behavior and the frequency and magnitude of artificial reinforcement can be slowly reduced.

Salkovskis and Warwick (1986) reported two successfully treated single cases of primary hypochondriasis using cognitive-behavioral methods. In another study, Visser and Bouman (1992) found that four of six hypochondriacal patients improved significantly following *in vivo* exposure, response suppression, and cognitive therapy. Interestingly, in this small study, exposure and response suppression (behavioral components) appeared to have accounted for more of the improvement than the cognitive component they used. The positive results of these series of single case studies were supported in a first controlled trial that showed cognitive-behavioral therapy to be superior to a wait-list control condition (Warwick, Clark, Cobb, & Salkovskis, 1996).

For patients whose main hypochondriacal concerns involve disease or illness phobia without significant conviction of having the illness, a more focused program of tension reduction (e.g., through relaxation), exposure to the feared stimuli, and prevention of checking and safety-seeking can be sufficient (Eifert, 1992, 1996). A representative example of this type of program was implemented by Warwick and Marks (1988). Their treatment employed exposure to feared stimuli, paradox (deliberate attempts to induce a panic attack), and response prevention such as banning reassurance-seeking and physician visits. There was a significant decrease in illness fear and increase in work and social adjustment for the group of 17 patients who were treated.

Overall, cognitive-behavioral treatments are very promising and prognosis for patients treated with such interventions seems more favorable than previously thought. More extensive and controlled studies are needed to examine what the most crucial treatment components are and to determine the mechanisms for their success.

6.24.6.3 Pain Disorder

Although there have been suggestions that treatment of pain based on psychodynamic principles may be effective (Adler, Zlot, Hurny, & Minder, 1989), empirical evidence has been scarce and not very compelling (Gamsa, 1994; Turk et al., 1983). Biofeedback (e.g., Budzynski, Stoyva, Adler, & Mullaney, 1973) and hypnosis (Sacerdote, 1970) used to be popular treatments for pain, in the 1970s in particular. These approaches, however, have been harshly criticized on a number of grounds (for a review, see

Turk et al.). Most importantly, critics claim that these techniques are ineffective when used alone, and any treatment effects are due to the unwitting inclusion of behavioral and cognitive treatment components (Turk et al.) We will therefore focus on cognitive-behavioral approaches to the management of pain.

According to operant principles, pain behavior is not an expression or side effect of a pain problem, instead it is the problem (Rachlin, 1985). Therefore, the goal of treatment is to extinguish maladaptive pain behavior and to teach and encourage the use of more adaptive pain coping strategies (Nicholas, Wilson, & Goyen, 1991). Treatment begins with a thorough functional analysis of current pain behavior and the environmental contingencies associated with that behavior. Once the consequences maintaining the maladaptive pain behavior are determined, attempts are made to reduce reinforcement for that behavior and to increase reinforcement for adaptive pain-coping behavior (cf. Fordyce, Roberts, & Sternbach, 1985).

In addition to changing a patient's maladaptive pain behavior, cognitive-behavioral therapy also attempts to alter associated thought patterns and the patient's perceived competence to deal with pain (Schermelleh-Engel et al., 1997). Pain management programs typically include: (i) decreasing demoralization through problem reconceptualization; (ii) enhancing outcome efficacy by motivating active patient participation; (iii) fostering a patient's real and perceived competence to deal with pain; (iv) breaking maladaptive behavior and thought patterns; (v) teaching skills and adaptive responses to problems; (vi) teaching self-attribution for change and success; and (vi) planning maintenance.

Cognitive methods involving imagery and distraction have often been added to pain management programs (Turk et al., 1983). Based on the assumption that pain is mediated by thoughts and images, patients are encouraged to create and focus on those thoughts and images that alleviate pain, while ignoring those that exacerbate pain. Particularly for patients who engage in few activities, behavioral distraction may be beneficial in more than one way. This technique involves the introduction of overt activities that require attention in order to be performed (i.e., hobbies). As clients continue with these activities, they frequently recognize the value of the activities beyond their role as distractors.

Although the cognitive-behavioral approach to pain management has been identified as an empirically validated treatment by the Task Force on Promotion and Dissemination of Psychological Procedures (Chambless, 1995), it is unclear which specific methods are most effective. In a review of the experimental literature, Turk et al. (1983) concluded that patients successfully use cognitive strategies, but the data "do not convincingly establish the efficacy of any cognitive coping strategy relative to the strategies that subjects bring to experiments, nor is there sufficient evidence to support the use of any one strategy compared to any one other" (p. 96). Others have raised more fundamental criticisms and argued that the effects attributed to direct cognitive manipulations could be due to associated environmental manipulations (Rachlin, 1985).

6.24.6.4 Conversion Disorder

An important first step in the treatment of conversion symptoms is their early recognition in which a physical examination plays a crucial role. In many cases, a positive diagnosis can be made on the basis of the rather atypical or bizarre symptoms. Since conversion symptoms vary widely across patients, treatment needs to be individualized. Identifying precipitating stressors is an important treatment strategy so that patients can be taught more adaptive ways of coping with these stressors. Occasionally, manipulation of the patient's social environmental is necessary to reduce the influence of secondary gain. Partners and significant others may have to learn how to reinforce the patient's nonsymptomatic behavior. Favorable prognosis seems to be related to acute onset, massive stressor, and a good premorbid psychological and medical condition (Kent et al., 1995).

6.24.6.5 Body Dysmorphic Disorder

Behavioral interventions for BDD aim at changing avoidance behaviors, reassurance-seeking, checking, and excessive grooming. Exposure *in vivo* is used to counter avoidance of social situations (meeting people, having a conversation, being in the spotlight), body image situations (wearing camouflaging clothing such as baggy pants, long hair, sunglasses). Patients are encouraged to expose themselves to social situations, rather than avoiding them and to observe the reactions of other people to their imagined deformity. Rosen (1995) suggests exposure assignments such as wearing trendy clothes, using make-up to accentuate features, standing closer to people, undressing in front of one's spouse. Response prevention may involve stopping looking in the mirror for excessive periods of time and refraining from the use of make-up and from inspecting skin blemishes.

There are few controlled treatment outcome studies for BDD, but several case studies and uncontrolled trials have been reported that have used systematic desensitization (e.g., Munjack, 1978), exposure and response prevention (Neziroglu & Yaryura-Tobias, 1993), and social skills training (Braddock, 1982). Schmidt and Harrington (1995) describe a successful cognitive-behavioral therapy in a 24-year-old male who was preoccupied with having small hands. Nine one-hour sessions with behavioral experiments aimed at challenging beliefs about size of his own hands and other people's attention to his hands. Treatment resulted in a decrease of BDD-related cognitions, distress and avoidance behaviors, as well as a decrease in Beck Depression and Beck Anxiety Inventory scores.

Recently, a first controlled study (Rosen, Reiter, & Orosan, 1995) compared the effectiveness of cognitive-behavioral therapy with a wait-list control condition in 54 female BDD patients. Treatment was conducted in small groups and encompassed eight two-hour sessions. Therapy was aimed at modifying dysfunctional thoughts about the patients' body image, the reduction of appearance-checking, and exposure to avoided situations. Results at post-test and four month follow-up indicated improvement in the active treatment condition on several measures of body image, whereas no such changes occurred in the control condition. Although the results of this study are promising, more controlled studies are needed to corroborate existing data and to examine the role of the various treatment components.

6.24.7 CONCLUSIONS

Unexplained and unexplainable somatic symptoms are very common in the general population. These problems are costly to the individuals concerned in terms of distress and financial expense as well as to society in terms of lost productivity and healthcare costs. Compared with other common psychological dysfunctions (e.g., anxiety and depression), our present conceptual understanding of the somatoform disorders is poor and satisfactory comprehensive models are still lacking. Moreover, for most of these disorders we do not have basic and reliable information on issues such as prevalence, gender differences, etiology, and treatment outcome.

One factor that has impeded a better understanding of the somatoform disorders is the unsatisfactory and somewhat arbitrary current *DSM* classification. We have noted a considerable degree of phenomenological and functional overlap in the problems of persons diagnosed with somatization disorder, hypochondriasis, and chronic pain disorder as well as overlap between somatoform and anxiety disorders. In fact, comorbidity of somatoform disorders with an anxiety disorder, depression, and general medical conditions are the rule rather than the exception. In view of the existing conceptual and diagnostic confusion, vagueness, and imprecision, we question not only the utility of the current criteria for and distinctions between somatoform disorders but also the wisdom of keeping hypochondriasis in particular in a section separate from the anxiety disorders.

Difficulty in relating the physical and psychological aspects of somatoform disorders has led to further confusion. Although we caution against an over-reliance upon medical diagnostic procedures and the explanatory power of current medical theory, diagnoses of the somatoform disorders are based upon the sophistication and accuracy of medical diagnostic procedures. Research and service delivery for patients would benefit from a more balanced approach that is not just focused on finding or excluding somatic abnormalities but one that combines current medical knowledge and assessment techniques with assessments of a patient's behavior, cognitive processes, and social relationships (cf. Fink, 1996). In our work with cardiac patients (Eifert et al., 1997) we observed how a simple reliance on one source of information (medical or psychological) was inadequate for many patients. Instead, it was the combination of sophisticated medical tests and psychological information that yielded the type of knowledge that was useful for recommending and designing the most appropriate treatment for the individual patient.

Hence, one of the most compelling conclusions arising from this chapter is that somatoform disorders cannot be adequately understood, assessed, and treated from a single perspective. Both the *DSM* classification system as well as research in the area could be improved by adopting a multidisciplinary approach and an integrated biopsychosocial perspective. For example, Mayou, Bass, and Sharpe (1995) propose a multidimensional classification of patients with functional somatic symptoms along five dimensions: (i) number and type of somatic symptoms, (ii) mental state (mood and psychiatric disorder), (iii) cognitions (e.g., symptom misinterpretations, disease conviction), (iv) behavioral and functional impairment (illness behavior, avoidance, use of health services), and (v) pathophysiological disturbance (organic diseases, physiological mechanisms such as hyperventilation). As indicated in the section on health anxiety, individuals may be assigned different positions on all of these dimensions across the various types of somatoform disorders. Rather than attempting to find the "correct diagnosis," we recommend assessing patients along the crucial dimensions involved in the regulation of maladaptive illness behavior and devising treatment programs based on such functional dimensional assessments. Beyond the number and type of physical complaints, some of these dimensions include the presence and extent of preoccupation with body and health, symptom misinterpretation, disease suspicion or conviction, disease fear, safety-seeking approach and avoidance behavior, focus and modulation of worry and fear, and pathophysiological processes.

Based on a multicausal and multidisciplinary perspective, there are several potentially fruitful lines for future psychological research into somatoform disorders such as an increased focus on information processing behavior (attribution, attention, and memory) and environmental contingencies for illness behavior (e.g., social, occupational, medical). Psychoneuro-immunological studies may help clarify particular aspects of the nature of the interface between pathophysiological changes, and individual responses to such changes as exemplified in some chronic pain research (cf. Flor et al., 1990). Although the past emphasis on the problems of patients with no demonstrable physical pathology was worthwhile and deserves continued attention, the gray area of persons with some organic pathology, bodily symptoms, and psychological distress deserves greater recognition and needs to be investigated more carefully.

Treatment programs and outcomes are likely to be enhanced further by an improved understanding of these problems from a multidisciplinary perspective. The need for an improved understanding and better treatments is even more pressing for those somatoform problems that have been particularly neglected in the past, such as somatization disorder, BDD, and conversion problems. The relative success of recent cognitive-behavioral treatment programs for persons with unexplained physical symptoms, health anxiety, or chronic pain is promising. These treatment successes may help change the common perception of healthcare providers that people with such problems are just a "pain in the neck" and invariably difficult, or maybe even impossible, to treat and may provide more hope for patients as well.

6.25.1 INTRODUCTION

The use of substances that alter mood, behavior, or cognitions has been a part of human life across numerous social contexts throughout history. Invariably, there are some individuals whose use of such substances may lead to abuse and eventual psychological, social, or physical harm. The fourth edition of the *Diagnostic and statistical manual of mental disorders* (*DSM-IV*; American Psychiatric Association, 1994) and the 10th edition of the *International classification of diseases* (*ICD-10*, World Health Organization, 1992) criteria for substance dependence owe much to the original description of the alcohol dependence syndrome (Edwards & Goss, 1976). These authors proposed a biaxial concept with dependence forming one axis, the other being alcohol-related consequences or disabilities. The elements first proposed for the alcohol dependence syndrome provide a framework for the description of psycho-active substance dependence in both major diagnostic systems.

Dependence was seen by Edwards and Goss as a cluster of behavioral, cognitive, and physiological phenomena which develop after repeated use of alcohol. The elements were persistent use in the light of harmful circumstances, increasing salience of alcohol-seeking behavior, narrowing of drinking repertoire, difficulties in controlling intake, relief use, and neuroadaptive changes producing tolerance and withdrawal symptomatology.

The *ICD-10* criteria for substance dependence are outlined in Table 1. Most of the components of dependence in *ICD-10* are to be found in *DSM-IV* and Hasin, Li, McCloud, and Endicott (1996) report excellent agreement between the two systems. One problem, however, with any diagnosis of psychoactive substance dependence is that it gives the impression of an all or none classification. This is not the case as there is continuous variation within all the elements, and so dependence should be seen as a continuum ranging from mild to severe. Mild dependence on alcohol could, for example, be regarded as a statistically normal condition. Nonetheless, the dependence syndromes as defined in the two major diagnostic classifications are robust and there is a body of factor analytic evidence that indicates that the elements form a single dimension, thus emphasizing the homogeneity of the syndrome (Davidson, Bunting, & Raistrick, 1989; Feingold & Rounsaville, 1995). This latter study also confirms that the dependence syndrome, as measured by *DSM-IV* diagnostic criteria, is factorially distinct from measures of the consequences of substance abuse in all drug groups. In other words, some people use drugs safely. Others, who may or may not develop symptoms of dependence, abuse drugs and encounter problems.

Thus drug abuse and its debilitating *sequelae* are not necessarily synonymous with dependence. Abuse has been defined by the Royal College of Psychiatrists (1979) as the use of a substance that "harms or threatens to harm the physical or mental health or social well-being of an individual." Harmful consequences can arise from prolonged and excessive drug use, but can equally occur as a result of acute intoxication in an occasional user, or indeed can be associated with the mode of administration of the drug. For example the recreational use of ecstasy at a Saturday night dance can have fatal consequences, and HIV infection is not restricted to severely dependent, long-term abusers. This chapter will focus primarily on the treatment of addictive behavior itself, rather than the harmful consequences associated with drug and alcohol abuse.

6.25.1.1 Scope of the Problem

The extent and demography of substance use is constantly changing. However, Babor (1994) draws a few broad conclusions about current trends. Use tends to be concentrated among the young and, with the exception of nicotine, the more addictive the substance, the more socially marginalized the user. The gender differential is diminishing and while the overall use of illicit drugs has increased in developed countries since 1985, alcohol sales have declined slightly (Anderson, 1997).

Since 1973 alcohol consumption in Europe has decreased from a pure alcohol equivalent, annual, per capita intake of 14 litres to 10.4 litres (Gual & Colom, 1997). Consumption has since stabilized and alcohol abuse continues to be a significant drain on economic resources. For example, it has recently been estimated that the total cost of the alcohol problem to the US economy is $70 billion per annum. For every $1 collected in taxes about $7 are spent on problems arising from alcohol abuse. Alcohol continues to be the major drug of abuse within the USA, where there are 18 million alcoholics compared with five million addicted to all other drugs combined (Asbury, 1995). Gelder, Gath, Mayou, and Cowen (1996) outline the results of two major US surveys which suggest a one year prevalence rate for alcohol abuse and dependence of 7–10% with a lifetime risk of around 14–20%.

Ramsey and Percy (1997) summarize the UK prevalence literature on drug use rather than abuse or dependence among the 16–29 year age group. In summary, about one-half of this group report using a prohibited drug ever, around one quarter in the last year, and 14% in the last month. In the surveys, it was estimated that 1% of respondents used heroin at some point in their lives. More direct approaches suggest that opiate use among the general, inner city population in London is around 2%. The Natural Comorbidity Survey in the USA (Kessler, McGonagle, & Zhao, 1994) found that one year prevalence for drug dependence for all adults was 3.6% while lifetime prevalence was 11.9%. Just under 40% in the US sample report using at least one illicit drug in their lifetime. It must be acknowledged that there is a range of prevalence estimation methodologies, which can render rather different estimates and which have been critically evaluated by Sutton and Maynard (1992).

Rather than detail the extent and pattern of use for each substance for different groups of people, some of the problems faced by epidemiologists in this field will be outlined using cocaine by way of illustration. One can measure population *use* of a drug in terms of quantity and frequency, or the extent of drug *dependence* or alternatively drug-related *problems*, such as physical illness, accidents, or emergency admissions. It is important to note that each of these indices can present different distributions and demographic correlates in the population. For example, most of a sample of 100 Canadian cocaine users described it as an infrequent, self-limiting behavior (Erickson & Weber, 1994). This finding was mirrored in a group of Dutch

Table 1 *ICD-10* criteria for substance dependence.

Diagnostic guidelines

A definite diagnosis of dependence should usually be made only if three or more of the following have been experienced or exhibited at some time during the previous year:

(i) A strong desire or sense of compulsion to take the substance.

(ii) Difficulties in controlling substance-taking behavior in terms of its onset, termination, or levels of use.

(iii) A physiological withdrawal state ... when substance use has ceased or been reduced, as evidenced by: the characteristic withdrawal syndrome for the substance; or use of the same (or a closely related) substance with the intention of relieving or avoiding withdrawal symptoms.

(iv) Evidence of tolerance, such that increased doses of the psychoactive substance are required in order to achieve effects originally produced by lower doses.

(v) Progressive neglect of alternative pleasures or interests because of psychoactive subtance use, increased amount of time necessary to obtain or take the substance or to recover from its effects.

(vi) Persisting with substance use despite clear evidence of overtly harmful consequences, such as harm to the liver through excessive drinking, depressive mood states consequent to periods of heavy substance use, or drug-related impairment of cognitive functioning; efforts should be made to determine that the user was actually, or could be expected to be, aware of the nature and extent of the harm.

nondeviant cocaine users (Cohen, 1994), in which only one in five proceeded to high use, while sustained problematic use was very much the exception. This distinction between use and dependence would seem to be manifest when samples are not drawn from biased sources, like the treatment or criminal justice systems. At its peak in the mid 1980s, 25 million Americans reported having used cocaine, while three million of these were considered to be dependent on the drug (Kleber, 1988). Reinarman, Murphy, and Waldorf (1994) conclude that dependent, harmful use of cocaine is more contingent on the social circumstances of users and the conditions under which the drug is taken rather than its pharmacological action on human physiology. It is important then to acknowledge the differing prevalence of use, dependence, and problems across sociodemographic groups.

The demographic profile of a drug can also change according to fluctuating availability, price, dependence potential of different forms of the drug, mode of administration, or public attitude. This has been elegantly illustrated by Pickering and Stimpson (1994) in their analysis of two centuries of cocaine use in the developed world. They trace the drug's changing demographic profile from the nineteenth century, when it was mainly taken in the USA by middle class women. Cocaine lost its nineteenth century status as a "tonic" and became a "social problem" when its use by soldiers could have affected the First World War effort. By the early 1960s, users of the drug came largely from the middle-aged, male, bohemian classes. When different routes of administration such as smoking and injecting as well as sniffing became available, the drug began to appeal to a wider group of users. As noted above, the widespread use peaked in 1985, but later the advent of crack cocaine meant that the profile of the typical user became more homogeneous; notably inner-city, socially marginalized young people. This change was mediated by a combination of lower price, more adverse public attitudes and greater dependence-forming potential. The evolving demographic profile of cocaine illustrates the problem of changing fashions in drug use. Babor (1994) notes that while drugs that have abuse potential seem to become a public health problem as a function of the variables outlined above, the decline of drug epidemics is related to many of the same variables.

6.25.1.2 A Longitudinal Perspective

In order to interpret treatment studies it is important to take account of the natural progression of dependence over time, although there have been surprisingly few studies that chart a typical drug-using career. This is a psychosocial construct, which takes account of various environmental influences and developmental changes that shape drug or alcohol use and must be understood in terms of the culture in which the individual lives. Treatment can be defined as a "set of facilitative events which may have the effect of edging an individual into a less destructive long-term career path." Edwards (1989) has similarly noted that treatment should be conceived of being, at best, a timely nudge or whisper in a long-term life course. Most people who successfully work through an addiction problem do so on their own without recourse to treatment. Indeed Prochaska, Di Clemente, and Norcross (1992) found that so-called self-changers often spontaneously employ strategies described in formal therapeutic systems. Klingemann (1994) encapsulated the importance of assessing treatment effects within the context of the natural history of a drug using career in his succinct definition of treatment as "assisted spontaneous remission."

Vaillant (1996) summarizes the long-term relationship between developmental changes and the onset, maintenance, and possible resolution of drug and alcohol abuse. When discussing resolution in particular, he concludes his review of longitudinal studies by arguing that variables such as maturation, treatment, a stable premorbid personality, or even social adjustment may be important in the short term but play a relatively limited role in eventual recovery. Rather, positive long-term outcome depends more on the eventual severity of dependence and "the individual encountering the right kind of naturalistic healing experience." There are very few established psychosocial predictors that can distinguish between those alcohol and drug users who achieve stable outcomes and those who do not. However, there seems to be a slowly emerging consensus in the literature that the key naturalistic factors that contribute to stable outcome include acquisition of an alternative behavior that acts as an addiction substitute, the discovery of new sources of hope and self-esteem and the development of new, stable, supportive relationships. The effects of treatment then must be understood against the backdrop of naturally occurring influences on the process of recovery. Vaillant (1983) outlines a useful set of ground rules for the ideal evaluation of the natural history of any treatment intervention. These include a follow-up period of more than five years, outcome assessment at multiple different times, the inclusion of multiple indicators of social functioning, minimal attrition, and controlling for post-treatment, environmental variables. Unfortunately, many treatment outcome studies reported in the literature fall short of this ideal.

6.25.1.3 Assessment

Before embarking on a treatment program, a sound assessment is required that will inform the choice of treatment goal and content. Information should be attained on the evolution of drug/alcohol intake, family history, patterns of current use, degree of dependence, the extent of drug- and alcohol-related problems, reinforcement parameters maintaining the behavior, and the opportunities within the client's environment for developing more adaptive responses. It is also important to assess the extent of any co-existing psychopathology.

There are numerous scales that have been developed for the assessment of various aspects of drug and alcohol abuse. Normally these instruments are very general and assess a composite of variables from a number of conceptually distinct areas; for example, dependence on the drug, craving, reasons for drug use, attitudes towards self and others, outcome and efficacy expectations, personal, occupational, and social consequences of heavy drug use, drug-taking history, and behavior when intoxicated. The most widely used screening questionnaire for alcohol abuse is the four-item CAGE (Mayfield, McLeod, & Hall, 1974). Other common screening instruments include the Michigan Alcohol Screening Test (Selzer, 1971), the Alcohol Use Disorders Identification Test (Saunders, Aasland, Babor, De La Fuente, & Grant, 1992) and the Drug Abuse Screening Questionnaire (Skinner, 1982). Various semi-structured interviews have also been developed to assist in the evaluation of a variety of drug and alcohol abuse variables. Examples include the Halikas–Crosby drug impairment rating scale for cocaine (Halikas & Crosby, 1991) or the Addiction Severity Index which assesses the severity of problems arising as a result of addiction to one or multiple substances (McClellan et al., 1992).

As noted above these are examples of instruments that measure a broad range of variables and can be used for general screening or assessment purposes. However, they do not provide the clinician with a pure measure of degree of dependence. This is an important predictor of eventual outcome and a number of scales have been developed that are specifically based on the alcohol and drug dependence syndromes. For alcohol, the most commonly applied dependence questionnaires are the Severity of Alcohol Dependence Questionnaire (SADQ) (Stockwell, Murphy, & Hodgson, 1983) and the Short Alcohol Dependence Data (SADD) (Davidson & Raistrick, 1986) in which there are 15 items that enquire about most of the elements of the alcohol dependence syndrome.

The severity of opiate dependence questionnaire SODQ was designed specifically, as the name suggests, to assess opiate dependence (Sutherland, Edwards, Taylor, Phillips, & Gossop, 1988). This instrument primarily focuses on the assessment of withdrawal symptoms and withdrawal relief behavior. As a result it may be difficult to adapt the SODQ to the measurement of dependence on drugs that do not produce a clearly defined withdrawal syndrome. The severity of dependence scale (SDS) is a five-item questionnaire designed to assess the degree of dependence experienced by users of different types of drugs (Gossop et al., 1995). It was devised to provide a short, easily administered scale and the five items are concerned with the psychological components of the drug dependence syndrome. The time frame of inquiry is the past year and the items are as follows:

(i) Do you think your use of (named drug) is out of control?

(ii) Does the prospect of missing a fix (or dose) or not chasing make you anxious or worried?

(iii) Do you worry about your use of (named drug)?

(iv) Do you wish you could stop?

(v) How difficult do you find it to stop or go without (named drug)?

The SDS would seem to be a promising research instrument which can provide an assessment of the degree of dependence experienced by users of a variety of psychotropic drugs, although as yet it is too early to evaluate its usefulness in clinical settings.

The assessment process will assist the therapist in tailoring a treatment program to the needs of the individual as well as elucidating on the most appropriate treatment goal. Gossop (1996) has provided examples of treatment goals which might include the following:

(i) Reduction of psychosocial or physical problems either directly or indirectly related to the drug problem.

(ii) Reduction of risky behavior associated with the use of the drug.

(iii) Attainment of controlled or nondependent use.

(iv) Attainment of abstinence from the problem drug.

(v) Attainment of abstinence from all drugs.

The issue of controlled use rather than abstinence has been debated at length within the alcohol field for many years and is perhaps symbolic of the difference between the more traditional disease approach and explanations of alcohol abuse generated from social learning theory. For this reason the debate was at times conducted at a more personal and anecdotal level than is normally the case in scientific discourse. The question is not "can some alcoholics drink normally?" since the literature is replete with examples to show that they can (Heather & Robertson, 1985), but rather which client will benefit most from abstinence and who would best be suited to a controlled drinking goal. More recently the term "harm reduction" has referred to interventions for drug abusers which involve controlled use rather than abstinence. A good example is the resurgence of interest in the methadone maintenance for opiate abusers and the reported associated benefits (Ball & Ross, 1991). Whatever the treatment goal, a key issue is the client's commitment to implementing real and permanent change in his or her pattern of drug or alcohol use. The following section will review some models that assist in our understanding of the stages in this decision-making process.

6.25.2 THE STAGES OF CHANGE

Psychotherapists have long been interested in the process of change. Pentony (1981) noted that most therapeutically induced change in cognition, affect, or behavior involves an initial destructuring with resistance being a central feature, an intermediate stage of conversion, and a final stage of restructuring. Janis and Mann (1977) analyzed how all sorts of permanent life decisions are made and they note that such change progresses through a number of stages notably reappraisal, considering the options, evaluation, action, and consolidation.

Within the addictions literature the idea of transitional stages or dispositional states has been developed by various authors. Tuchfeld (1976) interviewed a large sample of individuals who had recovered from alcohol dependence without recourse to formal treatment regimes, and on the basis of these interviews he proposed a two-stage model of change. The first is when defensive avoidance becomes untenable and a commitment to change is made. The second stage is one of maintenance of a new behavioral repertoire, which is characterized by personal vigilance and during which time the individual develops coping strategies to attenuate the possibility of relapse. Kanfer and Grimm (1980) also suggest a number of critical transition points as an individual begins to recognize the need for change, prepares for change, and eventually works towards maintaining change and minimizing the risk of relapse.

Arguably, the most influential model of change within the addictions field has been the so-called transtheoretical model of Prochaska and Di Clemente (1984) and Prochaska et al. (1992). The stages of change circle is now probably as familiar to addiction workers as Glatts' U-shaped curve. Orford (1992) likened the development of the transtheoretical model to a Kuhnian paradigm shift and suggested that it has helped rationalize the diversity of psychological interventions and place them in the context of the evolution of personal change. He argued that it allows us to see things from a fresh perspective and casts the process of change in an entirely new mold. The model is summarized in Figure 1.

The transtheoretical model was originally developed after detailed interviews of almost 1000 successful exsmokers, with success being defined as a period of abstinence of four or more years. Essentially during *precontemplation* individuals do not feel impelled to do anything about their behavior, perhaps as a result of ambivalence, denial, or selective exposure to information. As they become aware a problem exists, they enter the *contemplation* stage which is characterized by conflict and dissonance. *Preparation* is defined as a time when the individual drug user formulates action plans and is serious about his or her intention to alter behavior. *Action* is a period when overt changes are made, after which successful individuals enter the *maintenance* stage when new behaviors are strengthened and consolidated. The individual who does not relapse during this stage eventually exits the change system to termination, or in other words favorable long-term outcome.

The authors concede that a linear progression through the stages could be a simplification and acknowledge that on occasions a more cyclical pattern may be in evidence. People may move back from action to contemplation and precontemplation before eventually achieving long-term resolution of the problem. A number of questionnaires have been developed to assess the stage of change for drug abusers, including the eponymous Stages of Change Questionnaire (Prochaska et al., 1992) and the 12-item Readiness to Change scale (Rollnick, Heather, Gould, & Hall, 1992). Essentially these scales yield a score corresponding to the primary stage of change, which is indicated by the person's self-perceived intentions and behavior. Heather (1992) argues that the stages of change can now be reliably assessed and have considerable predictive validity. The key heuristic value of the model is that various categories of intervention are said to be differentially effective at each stage.

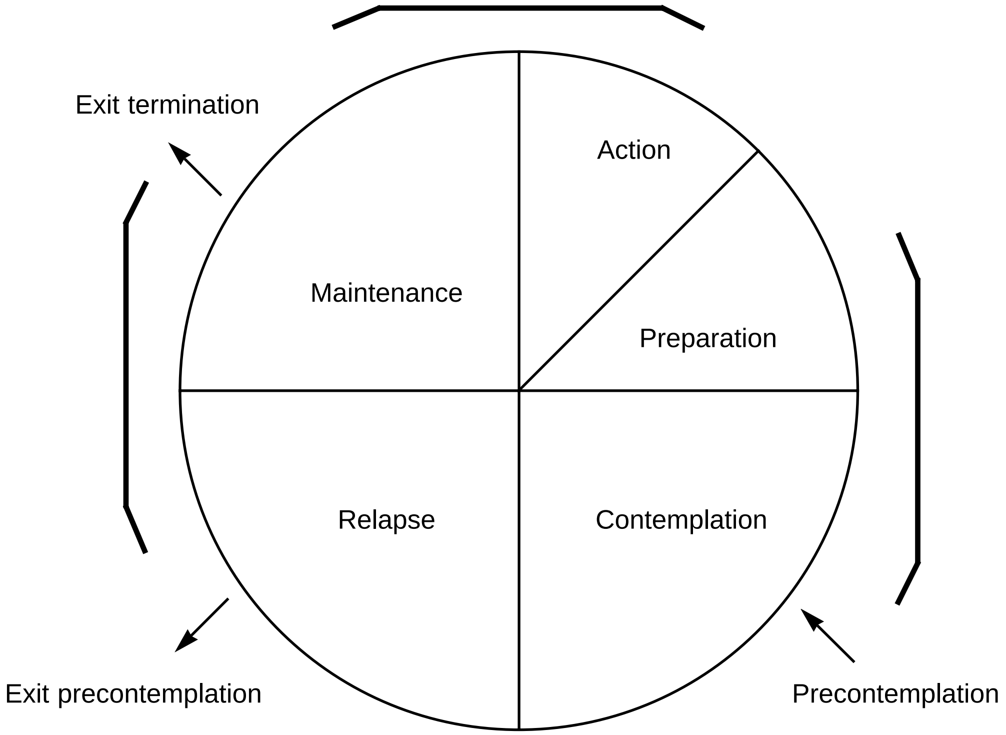

Figure 1 Stages of individual change. Source: adapted from Prochaska, DiClemente, and Norcross (1992).

Perhaps as a result of its intuitive appeal to practitioners and researchers alike the model escaped any considered criticism in the addictions literature for almost a decade. However, more recently a number of authors have questioned its validity and theoretical cohesiveness. Davidson (1992, 1998) commented that it is derivative and noted a number of empirical and conceptual weaknesses. Sutton (1996) felt that it was arbitrary to divide a behavioral/cognitive continuum into five mutually exclusive and exhaustive categories. He also reanalyzed some data on which the model is based and found that individuals did not necessarily progress through the stages of change in the sequence predicted by the model. Few subjects in fact showed a stable progression through three or more stages and, indeed, almost one-third of the sample remained in the same stage throughout the two year time frame. Budd and Rollnick (1996) applied a broadly similar analysis to scores on the Readiness to Change questionnaire, which revealed a continuum of readiness to change. These authors noted that while a stage model has greater intuitive appeal, a continuum model provides a better representation of the available data.

In a stinging criticism of the transtheoretical model, Bandura (1997) announced that stage theories are undergoing a dignified burial in psychology. He argued that this oversimplified stage view substituted a categorical approach for what is essentially a process model of human change. He suggested that people do not recycle through discrete stages but fluctuate in their struggle to exercise control over their health behavior. The stages of precontemplation and contemplation are simply differences in degree of intention while the subsequent stages are gradations of the very behavior that the model seeks to explain. For example, he noted that the action and maintenance stages are simply arbitrary subdivisions of the duration of the new abstinent behavior rather than differences in kind. In other words, this is simply a quantitative rather than a qualitative distinction. Less than six months abstinence from alcohol or drug use is said to define the action stage, while longer than six months defines the maintenance stage.

While all of these criticisms may be regarded as legitimate, the model continues to wield considerable influence in the addictions field and it is quite wrong for Bandura to argue that the stage models are undergoing a dignified burial. Terms such as contemplation and maintenance have become entrenched in addictions parlance and scarcely an article is written on treatment in addictions without reference to the stage of change model. Despite its shortcomings, the model of change does provide a structure to help us match different interventions with the albeit arbitrarily defined stages (Davidson, Rollnick, & MacEwan, 1991). Miller (1983) suggested that motivational interviewing is most useful for individuals in the contemplation stage, although it can prove beneficial for individuals in all stages of change. Behavioral and cognitive interventions can be optimally applied in the preparation and maintenance stages. In summary, despite the criticisms, this model remains a useful guide to assist practitioners in their choice of appropriate interventions.

6.25.3 PSYCHOLOGICALLY BASED TREATMENT METHODS

6.25.3.1 Motivational Interviewing

Motivational interviewing was described by Stockwell (1992) as the most important and influential therapeutic development within the field of addiction over the past decade. In his original account of motivational interviewing, Miller (1983) saw motivational problems as a result of the therapist/client dialogue, with the behavior of the therapist influencing the expectations, attributions, and behavior of the client. Denial was said to be a product of the more traditional, confrontational, therapeutic interaction. During motivational interviewing the individual is encouraged to reach his or her own decision about change, while the role of the therapist is simply to facilitate this process through clarification, advice when appropriate, accurate feedback, and empathy. The aim of therapy is to increase cognitive dissonance until a critical mass of motivation has been achieved and the individual is ready to move from precontemplation to eventual action. At this point commitment to real behavioral change is a likely outcome. Motivational interviewers operationally define motivation as the probability that a person will enter into, continue, and adhere to a specific change strategy and there is a strong emphasis on ambivalence resolution and the decisional balance. Essentially the client begins to present his or her own argument for change rather than being directed by a coercive therapist, while it is the therapist's role to set in place the optimum conditions for change. Specific motivational interviewing strategies and the treatment rationale have been detailed elsewhere (Miller & Rollnick, 1991).

Motivational interviewing is something of a misnomer in as much as it has little to do with contemporary cognitive theories of motivation. Rather it seems to be an example of the phenomenological approach to change and adapts the psychology of self-actualization to the promotion of personal change among alcohol and drug abusers. Miller and Rollnick (1991) contrast motivational interviewing with client-centered counseling by arguing, for example, that empathic reflection is invariably and noncontingently employed in client-centered counseling but used only selectively in motivational interviewing. Furthermore, they say that the good motivational interviewer is not afraid to proffer advice and will actively attempt to create discomfort and discrepancy rather than passively follow the client. Davidson (1996) suggests that this analysis is based on something of a caricature of the Rogerian position and that neo-Rogerian client-centered approaches are more active and task-focused than was hitherto the case. While the distinction between motivational interviewing and contemporary client-centered counseling may be little more than semantic, this is no bad thing. Motivational interviewing is an excellent example of a therapeutic system, squarely based on psychological principles, tailored to individual change in addictive behavior.

Rollnick, Heather, and Bell (1992) described a brief form of motivational interviewing that is beginning to be used to good effect in primary care settings. Miller and Baca (1993) found some evidence of better long-term outcome in a small group of patients who received a brief motivational interview over those who experienced a more directive, traditional style of interview. Baker, Kochan, Dixon, Heather, and Wodak (1994), however, could demonstrate no significant difference in HIV risk-taking behavior between a brief motivational interview and a nonintervention control condition. Kuchipudi, Hobein, Fleckinger, and Iber (1990) found brief motivational interviewing to be unsuccessful in reducing future drinking. Saunders, Wilkinson, and Phillips (1995) present a controlled trial of a brief motivational intervention with 122 drug abusers attending a methadone clinic. Subjects were randomly assigned to a motivational condition or a control, educational procedure. After six months, the motivational subjects showed significantly greater commitment to abstinence, reported more positive outcome expectancies and relapsed less quickly than the control group. The authors concluded that motivational interventions can be a useful adjunct to a methadone program. Heather, Rollnick, Bell, and Richmond (1996) reported a comparison between brief motivational interviewing, skill-based counseling, and a nonintervention control condition in a sample of heavy drinkers. While there were no significant differences between the intervention conditions in terms of a quantity/frequency measure at six months, clients who were evaluated at baseline as "not ready to change" responded better to motivational interviewing. This is interpreted as providing support for the view that motivational interviewing is most appropriate for those in the contemplation stage. Noonan and Moyers (1997) conducted a review of 11 trials that compared motivational interviewing with a range of other treatments. It seemed that motivational interviewing was uniquely effective if it succeeded in eliciting positive motivational responses without evoking resistance. It was, however, not particularly effective in the more severely dependent drinkers. Nonetheless the authors concluded that motivational interviewing was essential for all groups in the assessment interview as it reduced attrition rates.

The enormous popularity of motivational interviewing is in contrast to relative paucity of positive outcome studies. However, on balance it would seem that motivational interviewing strategies act in some way to resolve ambivalence and promote greater commitment to change.

6.25.3.2 Behavioral Interventions

Within the addictions literature the popularity of behavioral interventions has waxed and waned over the years. During the 1980s, there was a move away from such treatments, which were said to be reductionistic, mechanistic, and deterministic, and they were replaced by much more cognitively based multimodal packages of care. However, there has been a renewed interest in once-popular interventions such as cue-exposure and aversive conditioning which lend themselves to parsimonious explanation in the language of conditioning. Cue-exposure is based on the idea that a compulsion (a response to externally conditioned stimulus cues) will be reduced if the urge, which Marlatt (1978) defined as intention to carry out the behavior, is restricted. Cue-exposure can be understood in terms of both classical and operant conditioning. Drug responses, which can include withdrawal symptoms, antagonistic, compensatory, or agonostic effects, can become associated with the internal or external environment. Environmental cues are the conditioned stimuli which when presented in the absence of the unconditioned stimulus can produce this variety of responses. After classical conditioning, instrumental conditioning will occur if the conditioned responses become discriminative stimuli. Cue-exposure should in theory extinguish the conditioned response and so alter future behavior. In practice the client is exposed to cues which would usually trigger an episode of alcohol or drug use but if responses are prevented or controlled, this weakens the stimulus–response relationship.

Drummond, Cooper, and Glautier (1990) reviewed 20 years of cue-exposure research within addictions and concluded, rather disappointingly, that its efficacy must be questioned as there were so few methodologically sound studies that demonstrate its effectiveness in producing good quality, long-term change in the behavior of alcohol and drug users. More recently it has been suggested (Davidson, 1996) that this may be due to the possibility that treatment conditions employed by practitioners have not in fact taken account of the necessary contingencies required to promote maximum change in drug-using behavior. He suggests that there should be greater emphasis on individual differences in cue reactivity, only stimuli relevant to the individual should be included if generalization is to occur in the natural environment, and individuals should be instructed to focus on the most salient aspects of the stimulus. Finally there must be within-session habituation. In practice this means that there should be individually tailored cues of different duration with the termination of each session determined by clear evidence of habituation of the induced responses. Studies with opiate addicts (Powell, Bradley, & Gray, 1993), which have adhered to a theoretically driven treatment design, have produced promising results. Drummond and Glautier (1994) compared cue-exposure with a relaxation control treatment in a randomized control trial involving a sample of 35 severely dependent alcoholics. The cue-exposure clients had a total of 400 minutes of exposure to the sight and smell of preferred drinks over a 10 day period and showed significantly greater improvement on a range of consumption variables at six month follow-up. These recent positive results have tempered the rather pessimistic earlier conclusions of Drummond et al. Cue-exposure is an example of a treatment for which conditioning models neatly predict the optimum conditions for change, without recourse higher order cognitive explanations.

The second example of a treatment based explicitly on conditioning models is aversive conditioning, which was graphically described by Wilson (1991) as a strategy to decrease the appetitive allure of alcohol and drugs. The general criticism, that aversive procedures are inhumane and pejorative, is well known. However, in the context of the present discussion the importance of these interventions are that the conditions of maximum change can be theoretically specified. Cannon and Baker (1981) demonstrated the superiority of emetic therapy or chemical aversion over aversion produced to an electric shock and Elkins (1991) produced an elegant theoretical rationale for the consistent superiority of chemical aversion over electrical aversion for alcohol and drug abusers. Nevertheless, there have been surprisingly few well-controlled outcome studies that demonstrate the long-term efficacy of emetic therapy.

It is possible that most trials to date may not necessarily have adhered to the conditions that should promote maximum change. Of central importance is the temporal continuity between the conditioned and unconditioned response and it may be that some of the failures of emetic therapy are due to the fact that exposure to alcohol or drugs is introduced after the initial peak of nausea. Arguably, there is only one study in the addictions literature to date that is theoretically and methodological flawless (Cannon, Baker, & Wehl, 1981). In this study there was random assessment of clients to chemical aversion and nonaversion treatment conditions. Optimum contingency intervals were employed and a significant superiority of aversive conditioning was demonstrated at one year follow-up. Parloff, London, and Wolf (1986) found that for some alcohol abusers, aversive procedures were consistently better than more cognitively based interventions. Hester and Miller (1989) have outlined a treatment protocol for covert sensitization (verbal aversion). While this offers many practical advances, Elkins (1980) suggested that alcohol misusers who experience real, rather than suggested, nausea after the taste or smell of alcohol remain abstinent for longer than those who do not. However, it is probably fair to conclude, at the time of writing, that the use of aversive procedures for alcohol or drug misusers is relatively rare.

Heather and Stallard (1989) suggest that, generally, contemporary models of relapse perhaps underestimate the importance of classically conditioned craving in the relapse process. It is likely, therefore, that behavioural interventions, particularly cue-exposure, will become more important components of treatment programs for alcohol and drug abusers than they have been hitherto.

6.25.3.3 Relapse Prevention

Substance abuse has long been seen as a chronic, relapsing condition. A sound understanding of relapse management is perhaps the most fundamental issue in a discussion of the nature of treatment for addictive behavior. Relapse prevention is a generic term for a variety of approaches to the treatment of drug and alcohol abuse, primarily aimed at those in the maintenance stage of change. Edwards (1994) points out that it is important to remember that relapse prevention "does not imply a single theory of just one intervention technique but the deployment of a range of methods derived from a variety of behavioural and cognitive postulates" (p. 252).

The term relapse has been afforded a number of meanings by various authors. A lapse is seen by Gossop (1996) as being part of a transitional process which may ultimately lead to favorable long-term outcome, while a relapse is a return to the original pattern of drug intake. Relapse is not necessarily a discrete event that occurs at one moment in time, but rather it is the end point of the process of returning to former patterns of abuse. The process of relapse transcends the actual preferred substance of abuse. This was demonstrated in a seminal paper by Hunt, Barnett, and Branch (1971) who showed similar post-treatment, relapse/survival curves for alcohol, opiate, and nicotine abusers. Indeed, relapse prevention models have subsequently been applied to a range of behaviors about which an individual has made a commitment to behavioral control and has formulated a set of rules to govern this control. It was not until the 1970s that addiction researchers began systematically to examine the nature of the processes involved in relapse. Since then a number of leading models have emerged to guide our thinking and these have been reviewed by Connors, Maisto, and Donovan (1996).

Gloria Litman and her colleagues (e.g., Litman, Eiser, Rawson, & Oppenheim, 1977, 1979) saw relapse as a person–situation interaction. Of primary importance was the high-risk situation and the effectiveness and appropriateness of the individual's coping skills for dealing with it. Relapse was more likely in individuals who had few coping resources and who encountered a relatively large number of risk situations. Sanchez-Craig (1987) placed more emphasis on the individual's perception and appraisal of the risk situation rather than the situation itself. Relapse has also been systematically approached from what has been called a psychobiological perspective. Central to these models is the idea that relapse is precipitated by craving, which results in loss of control. Craving can be seen as a cognitive interpretation of the feelings of arousal associated with drug-related stimuli. Solomon's (1980) opponent process model defines craving as the interplay between positive and negative emotional states, induced by the substance. Tiffany (1990) formulated a model of drug use and relapse which highlighted the importance of automatic and nonautomatic cognitive processing. Automatic processes are characterized by speed, autonomy, effortlessness, and lack of conscious awareness. Examples are the urges and cravings generated by drug withdrawal or the reinforcing effects of drugs. Nonautomatic processes require conscious effort, the choice of competing strategies, the execution of preferred strategies, and the modulation of the strategy to take account of environmental changes. In order to deal with what Tiffany calls automatically induced urges and cravings, the individual must mobilize nonautomatic cognitive processes which require effort, attention, and intention and which can lead to overt behavioral and cognitive coping strategies.

Most relapse prevention programs therefore emphasize the importance of a broad range of cognitive and behavioral strategies which will attenuate the possibility of relapse. Arguably, the most influential model developed with the addictions field has been Marlatt's taxonomy of relapse precipitants.

Marlatt and Gordon (1985) presented relapse prevention as a set of principles broadly based on social learning theory. In a sample of over 300 individuals who used a variety of drugs, they were able to clarify the key relapse precipitants into two broad categories. The first includes intrapersonal precipitants such as negative and indeed positive physical and emotional states. For over one-third of alcohol and nicotine abusers and about one-fifth of heroine abusers the main relapse precipitant was a negative emotional state. The second category is interpersonal precipitants of relapse including relationship conflict and indirect or direct social pressure.

As part of a relapse prevention program, Marlatt and his colleagues suggest that individuals are taught to recognize the possibility of relapse. Essentially the client constructs a personal behavioral analysis and receives training in specific coping strategies. These can include broad-based skills training (behavioral rehearsal, assertiveness training), cognitive reframing (coping imaginary, reframing reactions to lapse), and lifestyle interventions (relaxation and exercise enhancement). All of these have been found to contribute to the effectiveness of a relapse prevention program. Clients are taught to recognize early warning signals and made aware of apparently irrelevant decisions that can increase the possibility of relapse. Emphasis is placed on the modification of cognitive distortions and the challenging of faulty beliefs or dysfunctional assumptions. For example, the *abstinence violation effect* is a distorted redefinition of lapse as relapse, so undermining the effectiveness of future coping behaviour. The Marlatt and Gordon relapse prevention program is therefore a combination of skills training, self-management, and cognitive interventions and the client is encouraged to practice these strategies using rehearsal, role-play, and homework tasks.

Carroll (1996) carried out a detailed review of 24 controlled trials that have evaluated the effectiveness of relapse prevention across a range of addictive behaviors including nicotine, alcohol, marijuana, opioid, and cocaine abuse. In the review, she included only those trials that specifically employed the relapse prevention model of Marlatt and Gordon (1985) and that were, in her opinion, methodologically sound. The outcome variables were primarily post-treatment patterns of substance use, rather than behavioral and cognitive indicators such as coping skills, self-efficacy enhancement, or social adjustment. The review concluded that there was some evidence of effectiveness of this type of relapse prevention approach across a range of substances, particularly smoking cessation, when compared with no treatment controls. However, its superiority over other active treatments and discussion control conditions was less consistent. The specific benefits over other treatments were in reducing the severity of relapses if they occurred and the approach seemed to be of most value for clients with more severe dependence or higher levels of psychopathology. The Relapse, Replication and Extension Project (RREP) was a major multicenter trial established to investigate the validity and reliability of Marlatt's taxonomy of relapse precipitants (Lowman, Allen, & Stout, 1996). Essentially the study confirmed the predictive validity of a modified version of Marlatt's taxonomy, although it did raise some questions about differences between proximal variables associated with time-limited relapse and variables that predict outcome in the longer term.

The relapse prevention model of Annis and Davis (1989) draws more explicitly on self-efficacy theory. The emphasis of this approach is on performance-based methods, notably the exposure to increasingly high-risk situations with continuing self-monitoring of efficacy expectations. In guiding the client through risk situations, Bandura's (1985) four factors that engender strong efficacy expectations are taken into account. First, the situation is challenging; second, to succeed in mastering the situation a moderate degree of effort is needed; third, the client is responsible and external help is kept to a minimum; and fourth, the success is described as part of a pattern of improved performance. The Inventory of Drink Situations helps identify the client's areas of high risk of relapse and the Situational Confidence Questionnaire measures perceived ability to cope effectively with a variety of drug-related risk situations. More recently Moser and Annis (1995) have emphasized the role of coping strategies in their cognitive behavioral model of relapse. They demonstrate that the survival of a relapse is strongly related to the number and type of coping strategies employed. Avoidance strategies are less effective in preventing relapse than active strategies, such as carrying out alternative activities, seeking support from others, positive self-talk, and cognitive problem-solving.

The relapse prevention models described above have been developed specifically within the addictions field, but their use has extended to a range of other clinical contexts, for example, anxiety management, eating disorders, and impulse control. However, there is also a series of models primarily used to inform research on health behavior decision making that emphasize the importance of cognitive processes as crucial determinants, not only in the abstention from risky behavior, but also the adoption of health beneficial behavior. These models have recently been employed within the addictions field.

One of the first and most influential was the Health Belief Model (Becker, 1974) which expressed the likelihood of positive health decision-making in terms of a cost–benefit analysis. This was superseded by the theory of reasoned action (Ajzen & Fishbein, 1980) and then came the theory of planned behavior (Ajzen, 1988). This latter model specified a number of variables that predict intention and behavior, namely control beliefs, subjective norms, and attitudes (a form of outcome expectations). These health belief models have been refined and developed by Ralph Schwarzer in his Health Action Process Approach (HAPA). This idea is now widely applied to the understanding of the fluctuating relapse/survival process of addictive behavior. Schwarzer (1992) comments that traditional relapse prevention approaches, such as that of Marlatt and Gordon (1985), have focused on the maintenance stage and have not promoted understanding of change strategies in the motivational and action phases of change. Essentially, within the motivation phase the individual forms an intention to adopt precautionary measures for changing risk behavior in favor of other behaviors. The action phase is an attempt to explain the relationship between intention and subsequent behavior, with emphasis being placed on action control and action plans. Estimates of the relative proportion of outcome variance explained by predictors of intention and behavior have been gleaned from a variety of sources. For example, outcome expectations and the perception of subjective norms contributed to about half of the variance in intention to stop smoking, but rather disappointingly stated intention to stop smoking accounts for only about 20–25% of the variance in actual observed long-term smoking abstention. However, when beliefs about personal efficacy are added to the model, its explanatory power increases substantially. Schwarzer concludes that self-efficacy expectation, or the belief that addictive behavior can be changed by mobilizing personal resources, is the most powerful predictor of intention and subsequent behavioral control. This view was supported by Kok, De Vries, Muddle, and Strecher (1990), who demonstrated that efficacy expectations alone could account for over two-thirds of the outcome variance of intention to stop and subsequent smoking abstinence. The total predictive effect of self-efficacy on the maintenance of health behavior exceeds the effect of any combination of other cognitive variables. Bandura (1997) agrees, and concludes his review of models of health behavior by noting that outcome expectations have variable effects, normative influences have little effect but efficacy expectations are constantly predictive.

In summary, the work of Annis, Schwarzer, Bandura, and others indicates that self-efficacy is emerging as the most powerful predictor of relapse/survival across a variety of addictive behaviours. Allsop, Saunders, Philips, and Cann (1997) suggest that training in coping skills is not enough, people must use the skills at the right time for them to be effective. The practice of coping skills improves self-efficacy so that the skills can be deployed in real-life risk situations. Furthermore, in recent years there has been much cross-fertilization of ideas between relapse prevention models developed primarily for substance abusers and more general models of health decision-making behavior.

6.25.3.4 Psychosocial Interventions

The prototypical, community self-group is Alcoholics Anonymous (AA) which was founded in 1935 by a serendipitous meeting between two American alcoholics, Bill W and Dr. Bob. Advice to attend AA remains part of many contemporary multimodal treatment packages for alcohol abuse. The principles of change espoused by AA are based on the Oxford group, a religious organization in the evangelical Protestant tradition (Bill W., 1957), which emphasized self-examination, the public admission of character deficits, restitution, pledge taking, and bible reading. Bill W. used this as a metaphor for the organizing principles of AA. At an AA meeting open sharing is encouraged and members admit their powerlessness over alcohol. The AA belief system is articulated in the 12 steps, which include the requirement of a searching personal inventory, commitment to a greater power, making amends to other people, and carrying the message to other alcoholics. Essentially, the AA model of addiction is one of an illness which can only be arrested by complete and life-long abstinence from alcohol; an illness that is said to be arrested but never cured. All attenders, no matter how long they have been alcohol-free, remain designated as recovering alcoholics. An analysis of AA-mediated processes of recovery suggests that motivation can be bolstered by the use of proximal goals (a day at a time) for everyone from the first attender to the 20 year abstainer. Emphasis is placed on role modeling, with constant recourse to a pay-off matrix in which the profit of staying sober is compared to the loss of being drunk. AA also offers, in the best relapse management tradition, alternative activity and new social networks. Much AA folk wisdom, such as not getting angry, tired, or bored; monitoring thinking tricks, and self-justifying statements, is the stuff of social learning theory. This prompted Edwards (1996) to compare an AA meeting to a cognitive behavioral workshop. In a small sample of AA attenders, Edwards et al. (1987) found that the most valued AA activity was hearing other people's stories and the least valued was the quasi-spiritual element.

Tonigan, Ashcroft, and Miller (1995) examined three AA groups in terms of perceived social dynamics and the relative emphasis on the 12 steps. The groups significantly differed in terms of cohesiveness, independence, and expressed aggression and it was found that 12 step discussion was lowest in the groups with the highest aggressiveness. In the light of these results it was suggested that AA need not be regarded as a homogeneous entity and a clear understanding of the variation among AA groups needs to be gained before we can make definitive statements about its effectiveness.

Davies (1992), in his attributional analysis of what he called the "myth of addition," argued that step one, which is an admission of powerlessness over alcohol, can absolve the individual of personal responsibility for his drinking. It minimizes the importance of a functional explanation of drinking behavior and Davies would say that it does not bode well for dealing with relapses should they occur. Ogbourne (1993) observed that we know little about the real long-term effectiveness of AA because as a matter of principle the organization keeps no records of the success and failures of its members. Furthermore as noted above, AA is less homogeneous than many people think. There is no doubt that AA, with its rigid explanations and emphasis on abstinence, does not suit most alcohol abusers and so attrition rate is high (Miller & McCrady, 1993). Edwards (1996) cautions "the evidence that AA works is suggestive and rests on the evidence of its popularity and seeming ability to meet need, rather than being a matter of proven fact" (p. 235). Nonetheless, for some people it is the belief that they are personally powerless over alcohol which can inspire faith and promote change (Keene & Raynor, 1993), and it is indisputable that the profound and international influence of AA belies its humble beginnings. Narcotics Anonymous (NA) was established in 1953. Christo and Franey (1995), in a six month follow-up of over 100 graduates from a residential program, found that NA attendance was inversely related to continued drug use and that spiritual beliefs or beliefs in the disease concept were not prerequisites for NA attendance.

The 12-step approach has been the basis of many community residential groups for alcohol and drug abusers. The 12 steps have been intermeshed with Maxwell Jones's (1956) pioneering models of therapeutic communities to produce concept houses, such as the original Phoenix House in New York, which provided long-term residential programs for addicts. Most of the emergent therapeutic communities in the North America and the UK can trace their roots back to the Phoenix House program. Contemporary Minnesota Model programs vary from group to group, but they are generally based on the first half of the 12 steps and include group work, lectures, and individual assignments, all of which can be preceded by detoxification. When appropriate there is family involvement, which will typically draw on the principles of Al Anon. DeLeon (1995) noted that not all residential drug abuse treatment programs are therapeutic communities and not all programs calling themselves therapeutic communities employ the same psychosocial models of treatment. However, the core themes of the drug and alcohol therapeutic communities are those identified over 30 years ago by Rapoport (1960), namely democratization, communalism, and reality confrontation. More recently, Norton (1996) has usefully reviewed the change process inherent in therapeutic communities and noted that it is difficult to specify the components of programs that best predict positive outcome. Smart (1976) reviewed outcome studies on community graduates and suggested that when recovery is defined solely in terms of patterns of drug use, outcome is fairly good. However when other outcome indices are employed, for example future employment, the results are less encouraging. Thorley (1981) reviewed a number of UK studies and concluded that therapeutic communities for drug abusers can greatly benefit some individuals but can actively harm others. It is also difficult to specify the optimum duration of care within such communities. For example, McCusker et al. (1995) compared a six month with a 12 month therapeutic community program for a mixed group of drug abusers and found no difference on a whole range of psychosocial variables and pattern of drug use at six month follow-up. While therapeutic communities may arguably be an effective rehabilitation system, they are relatively few in number and normally have quite strict entrance criteria, thus rendering them genuinely unavailable to all but a small minority of alcohol and drug abusers.

One final addendum to the AA story is the remarkable growth of the 12-step model within the USA for the "treatment" of a whole range of so-called appetitive disorders. Almost any potential problem from shopping to sex has a 12-step residential program for individuals prone to excess. This raises fundamental questions about choice, compulsion, and volition in our understanding of human behavior. Stanton Peele (1989) in his best-selling book, *Diseasing of America*, argues that there is now more "treatment" for everything and this inevitably undermines an individual's personal perception of control over his or her behavioral outcomes. Self-efficacy, so important in the treatment of any addictive behavior, is being diluted by what Peele calls the "therapeutic colonisation of our lives." One can only speculate how Bill W. and Dr. Bob would have reacted to the widespread use, perhaps abuse, of their simple approach. Maybe it has gone one step too far.

6.25.4 ISSUES IN TREATMENT

There are two key issues relating to the provision of treatment within addictions that have been the subject of much debate in recent years. The first relates to treatment intensity and the emergence of a plethora of so-called brief interventions for substance abusers. The second is the long-held assumption by most workers in the field that treatment should be tailored to the needs of the individual. In other words, which intervention for which client by which therapist is the most efficacious? Most of the ideas on parameters of treatment have been developed in studies of alcohol abuse and it is this literature that will primarily be covered in the following review.

6.25.4.1 Treatment Intensity

There have been over a dozen randomized controlled trials comparing the dose–response relationship in populations seeking psychological treatment for alcohol problems. In this context brief intervention is defined as one to three sessions of specialist treatment. A distinction should be drawn between minimal intervention or advice in a primary care setting and brief intervention within a specialist context.

The seminal study on brief intervention was reported by Edwards et al. (1977), who followed up a sample of 100 male alcoholics, all of whom had a three hour initial assessment. Half of the men then received a single session of direct advice and the other half were offered the standard intensive treatment package of the time which included medical interventions, introduction to AA, and hospital admission when appropriate. This study is well documented elsewhere but the key conclusion, which has influenced thinking on delivery of care to alcoholics, is that even after a 10 year follow-up there was no significant difference between the groups on a host of outcome measures. Subsequent, similar trials have more or less confirmed this finding. Bien, Miller, and Torigan (1993) reviewed this body of work and concluded that there are remarkably few differences between brief and extended interventions for treatment-seeking alcoholics. Well-planned, brief interventions produced similar outcomes when compared with more extended psychosocial interventions, with only two studies reporting a slight advantage for the latter.

The dose–response literature should, however, be interpreted with some caution. These studies are notoriously difficult to design and most of the controlled trails comparing brief with extended treatments have been subject to some criticism. Indeed Orford (1980) would concede that the Edwards' trial was by no means methodologically flawless. Heather (1995) has recently produced a useful evaluation of the literature. He argues that brief interventions tend to be seen as a homogeneous category and researchers, as well as practitioners, have paid insignificant regard to heterogeneity of this type of intervention. Furthermore, there are important differences between treatment-seeking populations as distinct from those that are selected as a result of opportunistic screenings. Heather also highlights the possibility of type two error, in that this family of studies is essentially proving the null hypothesis. It is an inferential error to conclude on the basis of a lack of significant difference between intensive and brief intervention that they are equally effective. Even with a large sample and sufficient statistical power, which is not the case in most of the trials, one can only conclude that there is no evidence of difference in effectiveness. Heather concludes his methodological critique by suggesting that it is at best premature, and at worst cavalier, to argue that highly dependent, treatment-seeking alcohol abusers gain as much from brief interventions as they would from more extended intervention.

There is, however, some merit in investigating the so-called active ingredients of brief interventions which seem to be, at least, relatively successful. Miller and Sanchez (1993) reviewed the protocols of a large number of brief interventions and isolated some critical conditions or key elements that facilitate change in addictive behavior. These can be summarized by the acronym FRAMES, representing feedback, responsibility, advice, menu, empathy, and self-efficacy. Essentially their findings would suggest that for brief interventions to be successful the client should be given realistic and accurate feedback about any drug-related impairment, emphasis should be placed on personal control and efficacy with corresponding attention to feelings of helplessness and powerlessness, good advice should be proffered, and the client should be given a choice of preferred change options. Finally, and arguably most important, therapeutic styles should be empathic rather than confrontational. While acknowledging Heather's caveats, the brief intervention literature does offer hope that for some drug and alcohol abusers, treatments that are structured along these lines could offer potential long-term benefits.

6.25.4.2 Treatment Matching

Almost invariably, any review of the treatment of addictive behavior concludes with a comment that intervention should be matched to the needs of the client. For example, Gossop (1996) notes that "for all types of drug problems that require treatment the intervention offered should be tailored to the needs and circumstances of the individual" (p. 159). Raistrick and Davidson (1985) say that "therapy should be tailored to the individual. What is useful for one person may be singularly inappropriate for another" (p. 154). Miller and Herster (1986) say that "clients should be matched to optimal interventions" (p. 27), and so it goes on.

However, these apparently obvious and laudable matching sentiments have recently been the subject of some scrutiny in the alcohol literature. Edwards and Taylor (1994) report a study that explored the interaction among treatment intensity, client characteristics, and 12 month outcome. There were no interactive effects and the authors conclude that the matching hypothesis was not confirmed. These data suggest that individual characteristics such as degree of dependence on alcohol or socioeconomic class, rather than client/treatment matching, may best predict outcome. Edwards and Taylor draw the tentative conclusion that relatively weak matching differentials are masked by developmental or environmental influences on the process of recovery.

Of particular interest in this regard is Project MATCH which Heather (1996) describes as the largest treatment trial ever mounted in the alcohol field. It was funded by the National Institute on Alcohol Abuse and Alcoholism and involved over 1600 clients tracked over a 15 month period. Meticulous attention was paid to all aspects of the trial design which essentially tested the relative merits of a variety of client/treatment combinations. Clients were randomly assigned to one of the three treatment modalities namely 12-step facilitation (TSF), cognitive behavioral coping skills (CB), and what was called motivational enhancement therapy (MET). TSF was based on the methods of Alcoholics Anonymous, but as it was only conducted for 12 sessions, did not include regular and life-long AA attendance as part of the treatment condition. CB was limited to 12 sessions of coping skills training, and MET was a four session program based on the principles of brief motivational counseling as outlined above. A variety of client characteristics were assessed, including motivational status, self-efficacy, degree of alcohol dependence, extent of social support, the number of alcohol-related problems, psychiatric morbidity, and cognitive impairment. Obviously the interactions between client characteristics and intervention were as important as any potential main effect between treatment conditions. The primary objective of the study was to determine which of various subgroups of alcohol-dependent clients would differentially respond to the three broad interventions. Additionally, the interaction of treatment location (inpatient vs. outpatient) with client characteristics and mode of intervention was examined.

In summary, the results indicated significant and sustained improvement on a range of outcome variables across the three main treatment conditions (Project MATCH, Research Group, 1997). In other words all three types of interventions were equally effective. With the exception of psychiatric morbidity, matching client characteristics with treatment did not enhance outcome. This one "match" seemed to indicate that outpatients with greater psychiatric morbidity responded better to CB than TSF. However, the overall conclusion of the study was that the general lack of robust matching effects means that practitioners need not take these individual characteristics into account when triaging clients to one or other of the three treatment interventions, despite their different philosophies. This is a counterintuitive and radical finding which will undoubtedly resonate in the alcohol treatment field for decades to come. Despite the methodological rigor, it may be argued that the 12-week protocol for CB and TSF and the four-session MET intervention do not reflect the range or richness of available interventions, particularly those based on social learning theory. The length of follow-up was only 15 months in this first Project MATCH publication and it could be that matching effects become manifest much later. Furthermore, it is unclear about the validity of cross-cultural application of these results. For example in the UK, Woodhouse and Davidson (1996) matched broadly similar interventions with motivational stage and while there was no significant difference in a quantity/frequency measure at one year, they found a small but significant matching effect at two years. Essentially contemplators responded relatively better to motivational interviewing, while those in the action stage were best suited to relapse prevention strategies. While this latter finding may not be clinically significant, it may add some weight to the possible criticisms of the Project MATCH trial regarding cross-cultural generalizability of the findings and the relatively short follow-up period.

6.25.5 CONCLUSION

A number of conclusions can be drawn from this review of cognitive and behavioral approaches to the treatment of addictive behavior. Most of the interventions described in the chapter have been offered to users of a range of substances. There has been a tendency to assume, not unreasonably, that the important component of any intervention is the cognitive and behavioral changes that accrue irrespective of the preferred drug of abuse. While this is intuitively appealing, it would seem that it is not always the full story. For example, at the risk of oversimplification, relapse prevention procedures are clearly useful for smokers, moderately effective for alcohol abusers, and have some variable effect, according to the available literature, as a treatment for cocaine abuse. There has, as yet, been no demonstrable significant improvement against a control condition for the relapse prevention treatment of marijuana use (Stephens, Roffman, & Simpson, 1994). Klingemann (1994) has speculated about possible reasons for these substance specific effects. He particularly notes that good quality, extensive social support may become progressively less accessible as the substance changes from cigarettes to alcohol to illicit drugs. While it is obviously important to elucidate on the general principles of change, there may be some merit in clarifying the possible value of substance specific interventions.

In answer to the question "Do psychologically based treatments of addictive behavior work?" most reviewers interpret the literature slightly differently. In the past there has been an overwhelming sense of what people termed therapeutic nihilism, based on the weak relationship between any type of intervention and eventual outcome. There is now, however, increasingly good evidence on the effectiveness of psychological approaches for addictive behavior. Moos, Finney, and Crankite (1990) in their studious review, concluded that treatment leads to substantial improvements in drinking behavior while acknowledging the importance of individual and social factors in the determination of outcome. The treatment outcome prospective study (TOPS) was a systematic evaluation of a heterogeneous group of treatment programs for a range of drug abusers. The TOPS study reported a general overall reduction in drug use over a three to five year period, as well as improvement in other psychosocial variables (Hubbard, Marsden, & Rachal, 1989).

While treatments based on psychological theory have been shown to be effective, no specific treatment approach has emerged as being consistently superior to the others. One problem with conventional, randomized controlled trials, particularly pertinent in the field of substance use disorder, is that the preference of an individual for one particular type of intervention over another is not taken into account in random allocation. A potential, future methodological advance may be greater use of designs like the partially randomized, patient-preference design advocated by Brewin and Bradley (1989) for the investigation of relative treatment effectiveness.

Finally, work on the interaction between treatment intensity and outcome in both inpatient and outpatient settings has been summarized above. Unfortunately at times this debate is conducted against a background of cost considerations rather than what is best for each individual. Room (1980) did well to remind us that the basic justification for providing treatment should be primarily for reasons of humanity rather than cost–benefit analysis.

6.26.1 INTRODUCTION

The twentieth century has been described as the "hinge of history." This description follows from the wide range of indications of social, economic, and environmental measures showing catastrophic change. One of these indications is the general public's level of involvement in gambling activities. Rowntree (1941) compared the standard of living of the residents of New York City in 1899 and 1936. In his analysis of leisure in everyday life, he reached the conclusion that gambling had grown enormously over that period of time. It is well-documented that, since 1936, gambling has continued its rapid growth not only in the USA, but throughout the world (Frey & Eadington, 1984; McMillen, 1996). In explaining the upsurge in gambling, the British Royal Commission on Lotteries and Betting (1933, p. 60) stated that, "One of the main causes, perhaps the most potent in the growth of gambling, has been the increased facilities for organized gambling." Similar views have repeatedly been expressed by contemporary observers of gambling (Connor, 1983; Cornish, 1978; Dickerson, 1984: Orford, 1985). However, the claim that the rapid growth in gambling is attributable to the legalization and the accessibility of gambling outlets may be considered false, or at least incomplete. Betting shops, gambling machines, lotteries, and casinos would be useless if ordinary people did not want to gamble. Even in societies where gambling has been prohibited, gambling games have nevertheless flourished (Dixon, 1996).

Prior to discussing why people want to gamble, it is important to specify what we are referring to when using the word "gambling." Research on gambling does not incorporate all risk-taking behavior, but only a limited range of such behavior. The essential nature of gambling is that money (or its equivalent) is risked on the uncertain outcome of an event, subject to certain conditions: (i) gambling occurs in a group context whereby after costs, taxes, and profits, the money wagered by the losers is redistributed to the winners; (ii) the redistribution of money is independent of any other commercial enterprise related to the gambling event. This definition excludes insurance such as life or property insurance. This definition of gambling is similar to those put forth elsewhere (Perkins, 1950).

It should be noted that all definitions of gambling appear to differ with respect to what is included or excluded. This problem can be overcome if the activities to be included are listed explicitly. In this context, three broad categories of gambling have been identified: betting, gaming, and lotteries. Betting refers to staking money on the outcome of an uncertain or future event; gaming refers to playing for money in a game of chance; and lotteries refers to the distribution of prizes by drawing lots. Although these three kinds of gambling have much in common at the structural level, they are completely different sociologically.

Claiming that people want to gamble does not advance our knowledge of gambling to any great extent, but immediately raises the question as to why people want to gamble. Understanding the motivation to gamble would appear to be central to understanding why people may gamble excessively, and can be expected to have an important bearing on how gambling-related suffering may be alleviated, diminished, or avoided.

This chapter argues that the motivation to gamble is seen as the acquisition of wealth and that the real problems in explaining gambling concern why it is that gamblers believe that money can be won. Because the belief of gambers that money can be won is erroneous, it follows that therapeutic methods which change the false beliefs of the gambler are more likely to be effective. This proposition is examined in detail.

6.26.2 MOTIVATION TO GAMBLE

Gambling explicitly involves the attempt to win money by staking money on an uncertain event. As a starting point in the attempt to understand the motivation to gamble, the acquisition of wealth can be assumed to be the prime motivation. The problem with this assumption is that all legalized forms of gambling are constructed so that the expected return is less than the sum wagered. For example, a roulette wheel with one zero takes in, on average, 1/37 of the money staked. Totalizators typically take in approximately 20% of the money wagered in racing (Ladouceur, Giroux, & Jacques, 1998) and lotteries typically take in approximately 40% of the revenue from ticket sales. These percentages vary from place to place and according to the structure of the distribution of prizes or returns, but in all cases the expected return on money invested constitutes a loss for the gambler. Thus, if the acquisition of wealth is the individual's goal, rational economic considerations would lead people to avoid gambling. This is the principal paradox of gambling: people, in attempting to gain wealth, engage in an activity which is expected to decrease wealth.

The gambling paradox can be resolved in two different ways: (i) accepting that the acquisition of wealth is the motivation, but the gambler misjudges the chance of winning; or (ii) rejecting the acquisition of wealth as the sole or central motivation involved.

The majority of theories of gambling behavior reject the acquisition of wealth as being the fundamental motivation for gambling behavior. However, cognitive theories of gambling assume that the acquisition of wealth is the primary motivation involved, and that people do not behave as they normally would with respect to that motivation. According to cognitive theories, gamblers hope to win money or believe that they will win money. Why people should hope to win or expect to win in the face of the adverse odds involved is the central concern of such theories.

By contrast, other theories of gambling assume that winning money is not the principal motivation for gambling. One cluster of such theories assumes that it is the amusement and excitement (the change in arousal level) that motivates gambling behavior. In the behaviorist form of these theories, the changes in arousal reinforce the gambling behavior (Dickerson & Adcock; 1987; McConaghy, 1980), whereas in more purposive theories, gambling has the function of changing mood (Brown, 1996) as when the excitement of gambling overcomes boredom. In some cognitive behavioral explanations, arousal retains a dominant role but must be coupled with appropriate cognitions (Sharpe & Tarrier, 1993). A second cluster of theories places more emphasis on personality dimensions and, more specifically, on impulsiveness (Blaszczynski & McConaghy, 1994). It is assumed that risk-oriented individuals are attracted to gambling and that problems arising from excessive gambling can be attributed to impulsiveness. Yet other explanations see the gambling as largely irrelevant: gambling is simply one possible means of escaping or avoiding stresses and associated anxiety elsewhere in the individual's life. All such theories assume that the principal reward for gambling is something other than money. Some support for this view comes from the gambling industry which regards gambling as a leisure activity in which the money expended by the gambler buys the gambling product. The product is understood to be the amusement and excitement of the gambling venture. Thus, gambling is viewed as a desirable activity in itself, similar to eating in a restaurant or playing a round of golf. The money spent by the gambler pays for the enjoyment received.

It might seem that these alternative explanations for gambling have a certain face validity. If, after all, it is unreasonable to expect to win money by gambling, then surely some other factor must be involved. When gamblers are questioned about why they gamble, the majority of answers concern amusement, excitement, and relief of boredom. By contrast, only a minority of individuals involved in betting and gaming state that they gamble in order to win money. The important question is whether or not the opinions of gamblers as to why they gamble should be accepted indiscriminately. A certain amount of validation of the data derived from other sources is a minimum requirement. Consider, for example, the claim that gambling is exciting and that the rewarding value of the excitement is the main reason why most people gamble. If this claim is true, then several implications follow:

(i) Behavioural observation should support the self-report data. Gamblers should appear to be excited when gambling. Excitement should be apparent on faces (laughing and smiling), in exclamations of delight, and in the general bodily tension and alertness.

(ii) Physiological measures should support the self-report data. Gamblers should exhibit raised levels of heart rate, blood pressure, and palmar sweating. Neurophysiological measures should also suggest general arousal.

(iii) Indications of excitement should not be highly correlated with winning. If excitement always accompanies winning and no other events within the gambling cycle, then it is not possible to know whether it is the winning or the excitement which maintains the behavior.

(iv) If an explanation of gambling in terms of the reward value of excitement is to be generalized, then the indicators of excitement should be present for all forms of gambling.

Surprisingly, there is very little evidence supporting any of these specific implications. Here, we briefly review the evidence.

Excitement is most easily observed in certain forms of betting and gaming, and among the winners of lottery prizes. Thus, the noise of the crowd at a race track reaches a crescendo as the leading horses reach the winning post. Similarly, certain casino games, such as craps and two-up, have been described as suitable for the extrovert in view of the manifest excitement of the players (Allcock & Dickerson, 1986). However, such observable excitement is not sufficient evidence. Observable excitement is less in off-course betting shops and may be largely absent among home gamblers with phone accounts. Furthermore, certain casino games, such as blackjack and pai gow, are traditionally played with a minimum display of emotion. In poker, the ideal involves an absence of genuine emotion. Thus, there are many examples of gambling situations in which no excitement is expressed.

Different measures of physiological arousal may be used in gambling research. Increases in heart rate have been reported for blackjack (Anderson & Brown, 1984) and changes in skin conductivity for slot machines (Sharpe, Tarrier, Schotte, & Spence, 1995) when players begin a session. It is likely that arousal increases at the beginning of all gambling sessions. However, excitement prior to gambling cannot be a reward for gambling. More importantly, arousal must be demonstrated to correlate with events within the gambling session. In a detailed study of slot machine gambling through time, Dickerson (1993) did not find any correlation between player arousal and the events within a session. Although variations in arousal have been demonstrated for certain gambling-related events, the failure by Dickerson to show that arousal is correlated with machine events in slot machines is an important obstacle for an excitement-based explanation of gambling. Furthermore, the low numbers of positive reports of arousal in relation to the wide range of gambling, casts doubt on the ability of excitement-based theories to have wide explanatory power. However, as discussed in detail later, arousal has been found to be associated with erroneous perceptions that create an illusion of control and result in the overestimation of the probabilities of winning. Interestingly, arousal decreased when erroneous perceptions were corrected (Giroux, Ladouceur, & Jacques, 1998).

By contrast with arousal and personality theories, cognitive theories of gambling assume that the acquisition of wealth is the primary motivation involved, and that people do not behave as they normally would with respect to that motivation. According to cognitive theories, gamblers hope to win money or believe that they will win money. Why people should hope to win or expect to win in the face of the adverse odds involved is the central concern of such theories.

6.26.3 DEPARTURES FROM NORMATIVE DECISION MAKING IN GAMES OF SKILL AND GAMES OF CHANCE

Some gambling games allow the players a range of decisions which can affect the outcomes. In such games, players may depart from optimal play by choosing alternatives with lower expected values. Skill then refers to the extent to which a player's strategy of choices approaches the optimal strategy. Gambling games involving skill include blackjack, poker, and sports betting. In all of these games, systematic departures from optimal play have been reported.

In blackjack, with optimal play, the expected value of casino blackjack is approximately -0.7% with variations from that figure depending on the specific rules of play that apply. Nevertheless, most players do not approach this figure in their play (Griffin, 1987; Wagenaar, 1988; Walker, Sturevska, & Turpie, 1995). Analysis of the errors in play shows that in general the players adopt strategies which are too conservative. Players tend to sit when they should hit, avoid splitting pairs when it is desirable, and take out insurance when it is unnecessary (Wagenaar, 1988; Walker, 1995).

Interestingly, the departures from normative play in poker tend towards risk rather than avoidance of risk. For example, players in five card stud tend to stay in the pot with a small pair when they should fold (Yardley, 1957). In draw poker, players will draw to hands with very small probabilities of success, and professional poker players prefer games in which the action is loose, that is, risky (Hayano, 1977; Yardley, 1959).

There are many systems for betting on horse races and, as the variations between the systems are great (Allcock, 1987; Beyer, 1993; Drapkin & Forsyth, 1987; Scott, 1982) and no more than one can be accurate, it follows that the majority of systems yield less than optimal decisions. More generally, betting patterns have been observed to vary across a race meeting with betting on the last race at the meeting being more risk oriented than betting on earlier races (Bird & McCrae, 1985). Recently, Ladouceur, Giroux and Jacques (1998) showed that regular punters, defining themselves as experts in horse races, could not provide a better rate of return than a random selection of horses.

In games of chance all alternatives have equal expectations, and thus there is no optimal method of play. Well known games of chance include lotteries, roulette, and slot machines. Since no optimal strategy exists for games of chance, players would be expected to expend no effort in trying to choose the best action—the most likely winning ticket in lotteries, the most likely winning number in roulette, or the machine most likely to pay out in slot machines. Nevertheless, players can be observed expending considerable effort in making these decisions (Griffiths, 1994; Wagenaar, 1988; Walker, 1992). To the extent that players believe that some alternatives are more likely than others in games of chance, their approach to betting can be regarded as not normative.

6.26.4 DEVELOPMENT OF GAMBLING PROBLEMS

Although a wide range of gambling-related problems have been documented (Walker, 1992), the classification of such problems has not been adequately developed. Classification of gambling problems can proceed from different perspectives and be based on different criteria. Most commonly, gambling-related problems are classified by the area in the gambler's life that is affected. Thus, Dickerson et al. (1995) divided gambling problems into those associated with the individual, the family, financial status, employment, and criminal activity. Lorenz and Shuttleworth (1983) divided the problems into personal, relationship, and financial. Similarly, Custer and Milt (1985) divided the problems into gambling, alienation, marital problems, boredom, legal problems, indebtedness, needs, and goalessness. Categorization of problems in this way has value at the level of assessment, but does not clarify the nature or source of the problems. Although overlaps must exist, it remains possible for a new researcher to divide the gambling-related problems differently into another, possibly equally useful, set based on areas affected.

An alternative approach, which places more emphasis on the genesis of the problems, assumes that the main cause of the problems is persistence with gambling despite the losses. Cognitive theories seek to explain why the gambler may persist with gambling until the losses become excessive. The next step in understanding problem gambling, which ultimately becomes labeled "pathological," involves analyzing the consequences of extreme persistence in the face of large losses. The central consequence, and possibly the core factor in causing gambling problems, is the financial loss. Although it may seem obvious that financial loss is a fundamental aspect of gambling problems, this perspective is sometimes not given the emphasis that would seem appropriate. For example, only four of the 10 criteria defining pathological gambling in the *Diagnostic and statistical manual of mental disorders* (4th. ed.; *DSM-IV*; American Psychiatric Association [APA], 1994) explicitly refer to the loss of money and the problems caused thereby. If the financial cost of gambling is emphasized, then many of the criteria for identifying pathological gambling can be understood as consequences of this common cause. Walker (1992), in his description of a sociocognitive theory of gambling, shows how the false beliefs of gamblers can lead to chasing losses, changes in mood, withdrawal and secretiveness, deceitfulness, irritation and anger, and foolish financial transactions. These changes at the individual level, coupled with the large loss in income, would be expected to impact on the family life, employment, and social life of the gambler.

Persistence with gambling causes not only financial loss, but also absorbs large amounts of the gambler's time. The time away can be expected to impact heavily on the family and on employment. Thus, to the group of spouses that includes "golfing widows" and "fishing widows," should be added "gambling widows." The impact on the family of excessive involvement in leisure activities or employment is common across activities and may be a cause of family argument and distress. However, it is likely that time away is for most gamblers and their families a minor factor compared to the financial losses suffered by the persistent gambler.

Apart from the loss of time and money, there is one further area of loss that is more difficult to quantify. Gambling can be characterized as a background of failure broken only by occasional success. According to cognitive accounts of persistence with gambling, the gambler holds a set of erroneous beliefs about the nature of gambling and the role of the gambler in relation to the gambling. Persistence with gambling increases the likelihood of overall loss. Thus the gambler is continually engaged in searching for explanations that maintain the core beliefs. The mass of evidence suggesting that the gambler's beliefs are erroneous is a continuing stress that can be expected to cause loss of self-esteem and, ultimately, depression. It would not be surprising to find that some gamblers show evidence of this stress in aspects of their physiology and biology (Blaszczynski, Winter, & McConaghy, 1986; Carlton & Manowitz, 1987; Sharpe et al., 1995).

One problem that general theories of gambling must confront involves specifying why only a minority of regular gamblers suffer problems to the extent that they ultimately seek counseling and treatment. Individual differences in persistence with gambling have been explained in terms of personality differences (Zuckerman, 1979), biological differences (Jacobs, 1986), and learning differences (Dickerson, 1984). However, perhaps the most valuable insights concerning individual differences in gambling have been provided by Orford (1985) and Oldman (1978). Orford asked the important question as to why not all gamblers continue gambling until their money is exhausted. If gambling is intrinsically rewarding, progression to gambling problems and pathology would be expected. Yet the majority of gamblers control their gambling sufficiently to avoid the potential problems. Thus, inability to exercise control over the desire to gamble is an important aspect of the genesis of gambling problems. Orford suggests that gambling problems may involve the conjunction of excessive appetites, incomplete socialization of control over appetites, and the availability of opportunities to gamble. Evidence for such a view of gamblers comes from observational studies of regular gamblers that show that most are able to modify their approaches to gambling when demanded by changed financial circumstances (Rosecrance, 1986). Oldman (1978) took the argument one step further by pointing out that gambling problems were a natural consequence of persistence with gambling. The label "pathological gambling" may thus be a means by which society negotiates the counseling and treatment of gamblers who are sufficiently unlucky that they lose too much (Oldman, 1978; Walker, 1995).

6.26.5 DEFINITION AND ASSESSMENT OF PATHOLOGICAL GAMBLING

Pathological gambling was officially recognized in 1980 with the publication of *DSM-III* (APA, 1980), and was classified as an impulse control disorder. The *DSM-IV* (APA, 1994) defined 10 criteria reflecting different aspects of pathological gambling. To assign the diagnostic of pathological gambling, the individual must meet at least five of these criteria. As mentioned above, if most individuals gamble without it being a problem, some will eventually become overwhelmed by the desire to gamble, will gamble more than they planned, and will eventually spend more money than they can afford to lose. Pathological gambling is characterized by a loss of control over gambling, lies about the extent of involvement with gambling, family and job disruption, stealing money, and continuous chasing of losses. From a clinical perspective, two elements are the most representative of a pathological gambler: continuous or obsessional chasing of losses; and family, job, and social disruption caused by gambling.

In our clinic (R. L.), we have recently adopted a multistep evaluation procedure. When an individual calls for help for a gambling problem, we return the call within 24 hours. During this first call, we ask the gambler to describe his main complaints and then administer the South Oaks Gambling Screen (SOGS). The SOGS is a 20 item instrument used in many prevalence studies around the world to identify the number of pathological or problem gamblers in the general population. It has been translated into many languages including French, Chinese, German, and Spanish. If preliminary data collected during the phone call suggests that the individual is a pathological gambler, a formal semistructured interview is immediately scheduled in order to identify the nature and history of the problem. Before starting this interview, the individual will be asked to complete questionnaires evaluating the following areas: depression, anxiety beliefs about gambling (Ladouceur, Arsenault, Dubé, Jacques, & Freeston, 1997), superstitous behavior (Ladouceur, Giroux, & Jacques, 1988), and problem solving abilities. The interview is divided into two sections and covers the following aspects: history of the gambling activities; motivation for the consultation; first contact with gambling; first problems with gambling; familial, professional, and marital problems; money lost and criteria of pathological gambling. The last step in our evaluation is the second administration of the *DSM-IV* in order for the therapist to confirm the diagnostic of pathological gambling. If the individual is diagnosed as a pathological gambler, treatment is offered and usually starts the next session after the evaluation procedure.

This procedure has many advantages. First, the gambler is contacted within the 24 hours after his call. Second, the telephone interview focuses on the gambling problem (description of the main complaints and the administration of the SOGS), thus setting the purpose of the consultation and the subject matter of further treatment, if necessary. Third, this assessment procedure provides relevant information about the different aspects of the gambler's life problems (family, job, social, legal, financial, etc.). Fourth, this procedure will provide useful data for the validation of various instruments, and on the characteristics of the patients who refuse or drop out of treatment. As will be discussed later, adherence to treatment is a major concern for professionals working with pathological gamblers. We need to identify the characteristics and the reasons of individuals who refuse treatment, drop out, or simply do not show up for the first session.

6.26.6 PREVALENCE OF PATHOLOGICAL GAMBLING

The prevalence of pathological gambling is the percentage of the members of a society at a given point in time whose gambling is pathological according to some agreed criterion. Nearly all studies of the prevalence of pathological gambling have used one or other of the two measures described: the *DSM-IV* criteria and the SOGS. Most of the research has been conducted in the USA by Rachael Volberg on a state by state basis (Volberg, 1996), although substantial numbers of studies have been conducted outside the USA, such as in Canada (Ladouceur, 1996), Spain (Becona, 1996), Australia (Dickerson, Baron, Hong, & Cottrell, 1996), and New Zealand (Abbott & Volberg, 1996).

Comparison of the data from the studies reviewed by the authors listed above is made difficult by the fact that the details of the designs varied considerably across research groups. Volberg and Ladouceur used telephone surveys, whereas the surveys in Spain, Australia, and New Zealand used door knock surveys. Becona used *DSM-III-R* criteria whereas other researchers based their conclusion on the SOGS. Although most research has adopted a cut-off of five on the SOGS for the identification of pathological gamblers, Dickerson has argued that the cut-off should be higher. Finally, the SOGS itself may not be a sufficiently accurate indicator of pathological gambling for use in the prevalence research (Walker & Dickerson, 1996). Thus, current estimates of the prevalence of pathological gambling must be treated with a degree of caution. Nevertheless, the available evidence suggests that the occurrence of pathological gambling varies from country to country. Walker and Dickerson note that the prevalence figures for pathological gambling are correlated with the average expenditure on gambling across countries. Thus, in countries in which a higher percentage of personally expendable income is spent on gambling, there is a higher reported prevalence of pathological gambling (Table 1).

Evidence of this kind strengthens the argument that gambling-related problems are primarily associated with the loss of excessive amounts of money. Theories of pathological gambling must explain why the gambler persists in gambling despite such losses. Cognitive theories assume that it is erroneous beliefs and inferences about gambling and the likelihood of favorable outcomes which maintains the behavior in the face of serious monetary losses. It follows that a cognitive approach to therapy is the one that will attempt to correct the erroneous thinking involved.

6.26.7 PSYCHOLOGICAL TREATMENT OF PATHOLOGICAL GAMBLERS

The central assumption of cognitive approaches to treatment is that the pathological gambler continues to gamble because they maintain an unrealistic hope that they will recover their losses if they persevere with the gambling. It is assumed that their erroneous beliefs about gambling, about the nature of predictability, and about their own special skills and knowledge in relation to predicting gambling events, conspire to maintain the gambling far beyond any reasonable limits. It follows that any correction of erroneous perceptions weakens the belief that losses can be recouped. However, alternative approaches to the treatment of pathological gambling are not based on these assumptions. There are in fact two main alternatives to the erroneous thinking approach: (i) the behaviorist orientation, based on the use of extinction processes; and (ii) the problem solving approach where the gambler is counseled in methods appropriate to solving problems causing the gambling. Both orientations assume that the central motivation is not avarice, but some other factor altogether. These two approaches differ in the level at which they assume the relevant processes are operating: molecular and below awareness for the behavioristic approach; conscious planned processes in the problem solving approach.

The behavioral approach assumes that gambling-based arousal is the central factor in the reinforcement process. It is assumed that the increase in arousal associated with gambling is positively reinforcing. With repeated gambling a whole range of associated stimuli become conditioned reinforcers. Approach to, and participation in, gambling in regular gamblers are triggered by a wide range of environmental features: the sight of the newspaper, driving the car, leaving work, the sight of money in the wallet, and so on. The wide range of factors associated with gambling is often referred to, at the macro level, as preoccupation with gambling. Treatment makes use of established learning theory principles involving extinction of the association between arousal and central conditioned elicitors. The most effective specific treatment program using the behavioral approach appears to be imaginal desensitization (McConaghy,

Table 1 SOGS scores and gambling expenditure across countries.

Country	*SOGS scores (% scoring 5+)*	*Expenditure on gambling (% of personal consumption)*[c]
Australia	7.1	1.6
New Zealand	2.7	0.9
Spain	1.5[a]	0.7
Canada	1.2[b]	0.5

[a] Means of estimates provided by Becona. [b] Ladouceur's data only. [c] Haig (1985).

Armstrong, Blaszczynski, & Allcock, 1983; Blaszczynski, McConaghy, & Frankova, 1991). Imaginal desensitization involves creating a list of specific gambling triggers for the individual. The gambler is taught standard muscle relaxation techniques. Finally, the gambler is asked to imagine the trigger situations one by one, each time accompanied by the relaxation procedure. In this way, the association of arousal with each of the triggers is extinguished. McConaghy, Blaszczynski and co-workers treated 60 pathological gamblers with the imaginal desensitization procedure, and a further 60 pathological gamblers by a range of other techniques (aversion therapy, relaxation therapy, and cue exposure). Of the 60 pathological gamblers treated by imaginal desensitization, only 33 could be followed up two or more years later. However, of these 33, 26 (79%) were gambling in a controlled way or not at all. In the control group, only 16 (53%) of the 30 followed up had achieved control or abstinence.

The problem solving approach refers to a general orientation towards treatment rather than a coherent orientation towards the causes of pathological gambling. The actual causes of the gambling are assumed to be a variety of factors determined primarily according to the implicit theories of the counselor. According to addiction counselors, the gambler is driven by intense urges to gamble repetitively and in a maladaptive way. Thus the problem solving approach is oriented to increasing the gamblers ability to cope with the urges and to provide action alternatives that can be used to redirect the energies involved into alternative less hazardous directions. Many counselors believe that the gambling is an escape from crises and dilemmas which cause the individual great anxiety. Thus the problem solving approach is oriented to dealing with these other issues for which the gambling is an escape. There is a considerable body of research suggesting that counseling approaches yield improvement within a before-and-after design (Walker, 1992), little research has been done in which alternative therapies are compared or control groups used. The evidence available suggests that significant improvement may occur in a group of untreated pathological gamblers in a six month period (Echeburua, Baez, & Fernandez-Montalvo, 1996). Thus the necessity for controlled trials with longer-term follow ups (two years or more, ideally) is apparent.

The cognitive approach to the treatment of gambling is based on experimental work demonstrating a wide range of cognitive errors made by gamblers in relation to gambling (Ladouceur & Walker, 1996). The research of Ladouceur and his colleagues in Canada suggests that the core cognitive error lies in the gambler's notions concerning randomness. The illusion of control and belief in the predictability of events that depend on the misconception of randomness are assumed to lead ultimately to the bizarre beliefs documented by Coventry (1997), Walker (1992), and others. Gamblers try to control and predict outcomes of games that are objectively uncontrollable. The illusion of control motivates them to elaborate strategies to win more money. However, all gambling is based on the inherent unpredictability of gambling events either through inadequate information, as in sports betting, or through the incorporation of randomness as in slot machines, casino games, and lotteries. It follows that if the erroneous perceptions and understanding of randomness in the gambler can be corrected, then the motivation to gamble should decrease dramatically. Our treatment programs have focused on erroneous cognitions concerning randomness as the most important targets for change. The whole range of erroneous cognitions, sometimes labeled "irrational thinking" and which constitute the illusion of control, are also important targets for change. Since persistent gambling induces a range of other problems these are also treated. The loss of money is associated with many of these problems. Training in problem solving techniques appears to be appropriate and necessary in some cases. Also, many gamblers often lie and isolate themselves in order to gamble, and so social skills training may be necessary to help the client to reestablish adequate social relationships.

In order to evaluate the effectiveness of cognitive theory for pathological gambling, a controlled study has been undertaken at Laval University. Four components were included in the therapy: (i) cognitive correction; (ii) problem solving training; (iii) social skills training; and (iv) relapse prevention. These components are now described and are followed by a case study which illustrates how these elements have been integrated in the treatment of a pathological gambler. Treatment is administered on an individual basis with one 60–90 minute session per week, over a period of 12 weeks.

6.26.7.1 Changing Erroneous Beliefs Concerning Randomness

Correction of the misunderstanding of randomness is the first goal of the treatment. Different approaches to this task are possible according to the characteristics of the individual. However, only the general guidelines will be described here. First of all, most gamblers are not aware of their erroneous perceptions of randomness. They spontaneously deny that they maintain such false conceptions. Increasing awareness of the actual way in which gambling events occur is a first step in enabling gamblers to recognize their misconceptions concerning the predictability of the game (Ladouceur & Dubé, 1997; Ladouceur, Paquet, Lachance, & Dubé, 1996). The patient will be asked to describe the evolution of their gambling habits, how they were betting at first, the changes in their betting as they became more familiar with the games, and to what extent they feel they have some potential control over certain games. By asking about the way to get an edge in the particular form of gambling involved, the gambler is invited to expose some of their errors in thinking. Inevitably, the gambler will describe strategies of play which assume that there is more predictability present than is in fact the case (Ladouceur, Paquet, & Dubé, 1996).

The therapist will ask the client to describe what they are saying to themselves when they gamble. In doing so, the therapist may ask the patient to answer the following questions: Why did you place one particular bet instead of another? How did you determine this bet? Are you trying to control the game by avoiding certain bets? Would you agree to switch poker machines in the middle of a session when the machine you are playing has not paid out for a long time? Would you agree to bet on any number at the roulette table? How did you pick the numbers that you did on the lottery ticket you bought this week? The main goal of these questions is to clarify the fact that the gambler is using some sort of information to predict an event which is independent of all other events and essentially unpredictable beyond its chance probability.

The therapist makes a distinction between gambling that involves events that are inherently unpredictable because of inadequate information (such as horse racing) and events which are random (such as lotteries or slot machines). The therapist then shows that inherently unpredictable events are essentially the same as random events. Then, explanation of the concept of randomness follows, focusing on the most crucial element: each turn is an independent event (Gaboury & Ladouceur, 1989; Walker, 1992). Since each event is independent, there can be no influence from one event to the next and no predictability across events. Furthermore, as the events cannot be influenced legally, there can be no strategies to control the outcomes of the game. The therapist will focus on the strategies used by the gambler in their preferred game, and draw attention to the specific strategies that imply a sequential relationship between outcomes or that the probabilities of specific outcomes can be altered. The therapist should focus attention on any verbalizations made by the gambler that suggest the existence of links between the outcomes of the games. We often tape record these sessions in order to capture and analyze all of the patient's verbalizations suggesting links between the outcomes of the games. This recorded material is used to increase the patient's awareness, and later on to correct faulty perceptions.

Another useful way to illustrate the erroneous links inferred between events is by tossing a coin with the patient. First the patient is asked to predict whether the next event will be "heads" or "tails" and to explain and justify his choice (Ladouceur & Dubé, 1997). Most patients will say that their choice is based on a 50/50 probability of each possible outcome, which is indeed correct. This exercise is carried out a few times in order to demonstrate that predicting heads or tails is such a simple game, and that all of the outcomes of the toss are independent. Gamblers will generally agree with the therapist. Then, in order to demonstrate the presence of erroneous cognitions during a gambling session, a simple test is performed.

The therapist writes down six consecutive outcomes of heads and covers them with a piece of paper. Once again, the patient is asked to predict the outcome of the next toss. After their choice has been made, the six previous outcomes are revealed and the patient is asked if they would like to change their prediction before the coin is tossed again. Whether they change their prediction or not, patients will examine this series of outcomes. The therapist then points out the fact, that although the gambler knew that every outcome of a coin toss is independent, they spontaneously examined past outcomes even though these are completely irrelevant. This simple behavioral exercise has proven to be very helpful for demonstrating to the patient how this tendency to link irrelevant events is very powerful. (Ladouceur & Walker, 1996, give an extensive discussion of this phenomenon.)

The notion of randomness is then explained in detail, illustrated by examples of the games played by the patient. The fundamental error is in believing that information may be used to establish links between outcomes and then used to place winning bets. Gamblers will erroneously perceive some elements of skill that, if used appropriately, enhance their probability of winning. This illusion of control explains why people bet more money as they become more familiar with a game, firmly believing that they have developed some skills that can be used profitably. During this first stage of treatment, it is brought to the patient's attention that in many studies, conducted with different games in different countries, more than 75% of the players' verbalizations are erroneous (Ladouceur & Walker, 1996). Literature detailing the frequent misconceptions of gamblers is also provided to the client.

The pathological gambler is then asked to identify their own erroneous perceptions. This is achieved through a variety of methods such as: asking the patients to describe what they are saying to themselves when gambling (see example below); simulating a game and having the gambler describe how they proceed in choosing their bets; and asking the patient to imagine a gambling session and describe out loud what they are thinking, using the "thinking out loud method" (Gaboury & Ladouceur, 1989). These sessions are also usually recorded. Some examples of erroneous cognition are: "If I lose four times in a row, I will win the next time," or, after one or two wins, "I am really getting better at this game, I know how to bet." We will often start by replaying the tape obtained within an earlier treatment session, to demonstrate to the clients their false beliefs about the notion of randomness. The clients will also be asked to listen to the tape at home and identify every erroneous perception, or irrational statement. It is important to note that the basic cognitive error involves the linking of independent events.

Finally, the last phase involves the correction of inadequate verbalizations and faulty beliefs. Patients will monitor their own verbalizations when they are thinking about gambling, when they have the urge to gamble, or when they are gambling if they have not yet stopped. The patients will (i) identify erroneous perceptions, (ii) evaluate and challenge the adequacy of these perceptions, (iii) replace these inadequate cognitions by adequate verbalizations, and (iv) assess the strength of their belief in the new cognitions. The recording of their own verbalizations made during a simulated gambling session may be used during this corrective phase by asking the patient to reformulate erroneous perceptions by an adequate verbalization. The success of this phase is normally required before addressing further issues. Our clinical experience and empirical data (see below) support the fact that other therapeutic components are likely to be unsuccessful unless the gamblers have developed an adequate conception of the notion of randomness and can apply this notion to their own behavior. If the illusion of predictability in gambling events is allowed to remain, relapse is likely to occur.

6.26.7.2 Problem Solving Training

Problem solving training is a second therapeutic intervention, used if the gambler shows poor problem solving skills when coping with excessive gambling activities. Problem solving training becomes an integral aspect of the treatment of the pathological gambler if the therapist and the patient identify that additional skills are needed to solve the actual problems related to excessive gambling. The therapist will introduce a problem solving technique (Goldfried & Davison, 1976) that involves the following five steps: (i) defining the problem, (ii) collecting information about the problem, (iii) generating different solutions, (iv) listing advantages and disadvantages for each solution, and (v) implementing and evaluating the solution. The patient learns how to cope with the difficulties related to gambling. For example, in order to have better control over spending, they may decide to pay their bills immediately after they are issued, create a budget, and carry only the amount of money they need.

6.26.7.3 Social Skills Training

If necessary, gamblers are also given social skills training in order to improve their social competence. The potential link between poor social skills and gambling activities is discussed with the patients. It is important to recognize that pathological gamblers may need more than usual social skills to deal with their relationship conflicts. For example, some gamblers needed assertiveness training in order to increase their ability to refuse invitations to gamble with friends. Role playing can be used to improve communication skills. This training focuses on the negative consequences of gambling and how the lack of good social skills is a contributing factor.

6.26.7.4 Relapse Prevention

Relapse prevention is based on and adapted from the relapse prevention model developed by Marlatt (1985) for alcoholics. The possibility of relapsing is always discussed with the participants. They learn to become aware of high risk situations (present or past) and the reasons why people return to gambling. Patients will describe their relapses, identify high-risk situations, and develop specific ways to deal with the situations. For example, carrying cash (as on pay days), stress, loneliness, and lack of social activities are common high-risk situations. Each situation is discussed in terms of the erroneous perceptions associated with gambling. Specific attention is drawn to the debt and to the likelihood that the debt will be increased if gambling is resumed.

6.26.8 EFFICACY OF A COGNITIVE/ BEHAVIORAL TREATMENT FOR PATHOLOGICAL GAMBLERS

Single case experimental studies have been conducted over several years to evaluate the cognitive/behavioral approach to treatment for adults and adolescents suffering from pathological gambling. The results were quite encouraging (Bujold, Ladouceur, Sylvain, & Boisvert, 1994; Ladouceur, Boisvert, & Dumont, 1994). The following control group comparison study was conducted to further assess the treatment's efficacy (Sylvain, Ladouceur, & Boisvert, 1997). Twenty-nine pathological gamblers participated in the study. The majority of gamblers were video poker players, whereas others gambled on horse races or casino games. Subjects were randomly assigned to a treatment or a waiting list control group.

The following dependent variables were used:

(i) *DSM-III-R*;

(ii) SOGS;

(iii) perception of control over the gambling problem rated on a scale of 0–10;

(iv) desire to gamble indicated on a 0–10 scale;

(v) self-efficacy perception evaluating their belief that they could refrain from gambling in high risk situations;

(vi) frequency of gambling in terms of the number of gambling sessions, the number of hours spent gambling, and the total amount of money spent on gambling during the previous week.

Results showed that treated subjects improved significantly compared to the control group. Treated individuals met fewer diagnostic criteria, reported less desire to gamble, and had a lower SOGS score. They also reported a significantly higher perception of control and self-efficacy. In order to provide clinically relevant results, the percentage of change and end state functioning (comparing post-test scores to a criterion score) were calculated. Among the treatment group, 12 of the 14 participants improved by 50% or more on three dependent variables, and on the end state functioning criteria, in comparison to one of the 15 participants in the control group (85% success rate). Finally, six and 12 month follow-up measures indicated that the therapeutic gains were still present, confirming the long-term effects of this therapeutic program. The following case study illustrates the procedure described above.

6.26.8.1 Case History

Peter is 43 years old, married, and the father of two adolescents. He is currently working as a civil servant. He has been playing video poker for four years. At the time of his consultation, he was playing three times a week on average, which resulted in monetary losses of $350–500 per week (Canadian).

Peter started gambling when two of his colleagues invited him for a drink after work. As soon as they entered the bar, the two colleagues, both video poker players, showed Peter how to play the game. After an initial bet of $10, Peter won $125. During the following weeks, he developed an interest for video poker and played often. He occasionally made significant wins, and started believing that video poker was a good way to make money. After six months, his gambling became so intense that he had to use his personal credit and borrow money to cover his losses.

He progressively became obsessed with gambling. He accumulated increasing debts and was constantly preoccupied by the need to recover his money. He neglected his wife and children more and more each day. He lost his motivation to work, he often arrived late after having spent the lunch hour gambling or, he left early in the afternoon in order to play. His spouse did not know about her husband's gambling habits. She began to worry about his repeated lateness in the evening and his incapacity to pay the bills before the due date. She questioned and doubted Peter's justifications for his prolonged absences. Tension and conflicts became commonplace within their relationship. Peter's urge to play increased with his need to recover the lost money so that he could pay his bills, and in order to escape the climate of tension reproaches in his relationship with his wife.

After four years of excessive gambling, the losses were enormous. His absences from home became no longer justifiable and lying was frequent. One day, his boss, worried about Peter's diminished productivity, asked him the reasons for this change. Confronted with the possibility of losing his job, Peter had no choice but to admit that he had a gambling problem. He also decided to tell everything to his wife. Finally, he decided to seek treatment. A diagnostic of pathological gambling was made by the therapist and confirmed by a second experienced therapist who listened to a tape of the first session. The goal of the first intervention was to evaluate his motivation to change. Peter listed the advantages of stopping gambling and the negative consequences the game has had on his life. Monetary losses, professional and marital problems, and stress were examples of the negative consequences. Also, the return to a normal financial situation, general well-being, and better relationships with the people around him were the main advantages formulated by Peter to stop gambling.

6.26.8.1.1 Identification and correction of faulty cognitions toward gambling

Considering that one of Peter's motivations to gamble was to make money rapidly, it was important to provide him with factual information concerning gambling, and to identify his erroneous cognitions. The therapist asked him to imagine his last gambling session and try to identify his thoughts and the triggering events. Peter reported the following sequence. He left the office and drove toward his usual gambling place instead of going home as he had initially planned. He reported having this reaction instantly, without thinking, as if someone had told him what to do. The therapist had Peter focus his attention on the sequence of events that took place immediately before leaving his office. He was asked to remember what was going on and what he was thinking at that specific moment. Peter remembered putting his documents in order and, by accident, seeing the bills for his credit card that were overdue. The therapist inquired about the thoughts associated with finding unpaid bills. Peter answered that he suddenly felt panic and became very tense. When thinking back on the feeling of panic, he identified the links between this feeling and his unpaid bills. Peter panicked because he did not have the money to pay his bills. This made him so uncomfortable that he wanted to get money to pay them as fast as he could. The therapist finally asked him what he said to himself following this discomfort, and how was he going to solve his problem of obtaining money? At that moment, Peter became aware that he strongly believed that the best way to get a lot of money in a short period of time was by gambling. He realized that this was his motivation to gamble on this last occasion.

The therapist discussed the probabilities of winning, and the negative monetary expectancies of the games which would inevitably result in losses in the long run. The therapist explained that no strategies could be used by the player to win, and that the urge to recover the lost money was, in fact, just an illusion that leads to a vicious circle which can only end in loss. By questioning and confronting Peter's erroneous cognitions over several sessions, he started to realize that thinking he will win money is not realistic. Peter learnt to replace erroneous cognitions with appropriate ones, and to question his gambling habits (e.g., "Why do I feel like playing?" "I want to make money ... is this realistic?" "What could happen to me if I play? I risk further loss." "And if I lose, what will happen? I want to recover my money." "Can I really win?" "Even if I win tonight, it will never be enough to compensate for all the money I have lost." "The longer I try to win, the more likely I am to lose.").

6.26.8.1.2 Problem solving and social skills training

This component was used to modify behaviors related to excessive gambling. Peter mentioned going to the bank machine to check how much money he had left in his banking account. This compulsive checking triggered cognitions related to his lack of money, and the need to win more and gamble. Peter became aware of the sequence of these behaviors and realized the links between this checking behavior and his gambling activities. He resolved to stop checking his banking account. Peter also had to modify other relevant behaviors that stimulated gambling such as keeping less cash money with him, not carrying his banking and credit cards, and avoiding bars with video poker machines. Finally, the involvement with new activities, such as sports and family activities, helped Peter to reorganize his timetable and to replace the time spent gambling with less financially damaging activities.

6.26.8.1.3 Relapse prevention

By learning to identify situations with a high risk of triggering a relapse, and by analyzing situations which led him to gamble, Peter developed cognitive and behavioral strategies needed to refrain from gambling.

6.26.9 EVALUATION OF A COGNITIVE TREATMENT FOR PATHOLOGICAL GAMBLING

Following the positive results obtained through this controlled study, it was decided to evaluate the specific role of correcting the fundamental cognitive error about the notion of randomness. From a theoretical and clinical perspective, it was believed that this component was the crucial variable in the maintenance of excessive gambling. The efficacy of a cognitive treatment for pathological gamblers was assessed based on the correction of erroneous cognitions concerning the notion of randomness and, more specifically, through the modification of the gambler's tendency to link independent events when gambling.

Five pathological gamblers from the population described above participated in this study (Ladouceur, Sylvain, Letarte, Giroux, & Jacques, in press). A single case experimental design across subjects was used to assess the efficacy of the treatment. Cognitive correction included four components:

(i) Understanding the concept of randomness—the therapist explains the concept of randomness, independence among events, the impossibility to control the game.

(ii) Understanding the gamblers' erroneous cognitions, mainly the difficulty to apply the principle of independence among events. The therapist explains how the illusion of control contributes to the maintenance of gambling habits.

(iii) Awareness of inaccurate perceptions.

(iv) Cognitive correction of erroneous perceptions.

The dependent variables were the same measures used in the study described previously. Results indicated that all subjects, except one, increased their perception of control and reduced their urge to gamble, thus supporting the prediction that a cognitive treatment, based on the correction of erroneous perception about the notion of randomness, decreases pathological gambling. The treatment outcome of this intervention provided positive results equivalent to those obtained by a multicomponent intervention. Therefore, cognitive correction of erroneous perceptions toward the notion of randomness is likely to be the key element in the treatment of pathological gambling. We are now replicating this study with a greater number of subjects, using a controlled group comparison design. In conclusion, these therapeutic interventions, with an 85% success rate, open new avenues for the treatment of pathological gambling.

6.26.10 COMMON DIFFICULTIES IN THE TREATMENT OF PATHOLOGICAL GAMBLERS

Clinicians who have treated pathological gamblers have been confronted with a number of difficulties. We will briefly mention the most common and difficult ones encountered over the years in our clinic where approximately 200 pathological gamblers have been interviewed. The first and most important issue is treatment compliance. Very often, individuals will ask for an appointment but, without canceling, will not show up. They frequently drop out after one or two sessions, or will simply decide to terminate treatment after a few weeks of abstinence, thinking that their problem has been solved. There are no obvious solutions to these matters. Our clinical experience has led to the development of a series of procedures used to improve treatment compliance.

First of all, when an individual contacts us, we return the call within 24 hours, conduct a brief telephone interview, and administer the SOGS. If the individual appears to be a pathological gambler, an appointment is scheduled within a week at which point we conduct a structured interview and administer a series of questionnaires. If therapy is undertaken, the therapist will inform the patient that compliance is a major difficulty for pathological gambling and explore ways to overcome this problem. Furthermore, the patient will sign a contract indicating that they agree to participate for at least 10 sessions, and that if they are unable to attend, they will call ahead of time to cancel the session, that they will pay one session in advance, and that after two nonmotivated absences, treatment will be terminated.

A second difficult issue is determining whether the goal of the treatment should be controlling the gambling or abstinence. Many pathological gamblers ask that the goal of treatment be controlled gambling. Some will be very convincing and will put forth appropriate and rational arguments. We have often caught ourselves spending many sessions discussing this difficult subject without finding a solution. Gamblers suggest that controlled gambling is the main goal, simply because they cannot see themselves abstaining from this activity, or simply because they are not ready to stop gambling. Our approach on this matter is to consider abstinence as the main goal, and then once it is achieved, the matter can be reconsidered. In a few cases, instead of losing the patient, we have accepted controlled gambling as the main goal of treatment. However, this solution should never be accepted except as a last option.

The third difficulty is identifying erroneous perceptions towards the notion of randomness as discussed above. Often, pathological gamblers will simply deny that they have these misconceptions. The best way to pursue this matter is to design some behavioral experiment to facilitate the identification of erroneous perceptions. Gamblers deny these perceptions because they are not aware of them.

6.26.11 CONCLUDING REMARKS

This account of pathological gambling takes a cognitive perspective. It is assumed that pathological gambling occurs when the gambler persists in gambling, despite the losses involved, believing that ultimately the losses will be recovered and money will be won. These false beliefs of the gambler are maintained by the inadequate knowledge of the probabilities of success and the erroneous interpretation of the notion of randomness. If this account of the motivation to gamble is correct, then it follows that pathological gambling can be treated effectively by correcting erroneous beliefs of the patients. This chapter presents data supporting this theoretical position.

6.27.1 SEXUAL DYSFUNCTION

The term "sexual dysfunction" refers to a disturbance or impairment in sexual functioning. Sexual dysfunctions are usually contrasted with sexual deviations, or called "paraphilias." The latter are seen as a disturbance in the *direction* of one's sexual interest or desire, rather than of *functioning*. Thus paraphilias include paedophilia (sexual interest in children), fetishism (sexual interest in inanimate objects), and so on. Dysfunctions, on the other hand, are failures or problems in the actual sexual functioning, for example, difficulty in obtaining an erection, or failure to reach an orgasm.

It must be noted, however, that there can be overlap and interdependence between sexual dysfunctions and paraphilias. A man complaining of erectile difficulties in coital activity with adult partners may get strong erections in paedophiliac acts. Equally, a man presenting with, say, fetishistic desires for rubber or leather may also have erectile difficulty when he is not in contact with rubber or leather garments (de Silva, 1995). This overlap between these two types of sexual problems is important to recognize and take into account in clinical settings.

A further consideration is the link between sexual dysfunction and marital or relationship problems. Both clinical and research data show that the two areas are often related. Rust, Golombok and Collier (1988) reported that sexual dissatisfaction in the male partner strongly correlated with a poor marital relationship as perceived by both partners. The relationship between the two areas is not an invariant one, nor is there any clear evidence of the direction of causation when there is a link.

The prevalence of sexual dysfunction is hard to establish, as epidemiological studies are scarce. Masters and Johnson (1970) estimated that half of all couples in the USA have a sexual dysfunction. Spector and Carey (1990), who undertook a full review of the sexuality, psychopathology, and epidemiology literature, concluded that sexual dysfunctions may be very common. A major problem is that the presence of a sexual dysfunction is not always distressing to, or seen as a problem by, couples or individuals. The much-cited study of Frank, Anderson and Rubinstein (1978) provides some interesting data. Well over half the women and nearly half the men in this survey of 100 happily married American couples reported sexual difficulties, yet most were satisfied with their sexual life. Similar findings have been reported in a Swedish study (Nettelbladt & Uddenberg, 1979) and a British investigation (Reading & Wiest, 1984). This highlights another key issue. Sexual dysfunction is not an all-or-none affair; there are varying degrees of difficulties. The way they are perceived varies; occasional erectile failure may be seen as a perfectly acceptable situation by some men and their partners, while it may bring other men to a clinic seeking help. There are also major differences in sexual functioning in relation to age. Inability to obtain an erection increases progressively with age (Feldman, Goldstein, Hatzichristou, Krane, & McKinlay, 1994; Weizman & Hart, 1987). In the Kinsey survey (Kinsey, Pomeroy, & Martin, 1948), it was found that less than 1% of males had erectile dysfunction before the age of 19, increasing to 25% by the age of 75.

6.27.2 CLASSIFICATION AND DIAGNOSTIC ISSUES

Sexual dysfunctions have been classified in different ways by different authors in the past (e.g., Bancroft, 1989; Hawton, 1985), but in the 1990s a consensus has been emerging. The current classification offered in the *Diagnostic and statistical manual of mental disorders* (4th ed., *DSM-IV*) (American Psychiatric Association [APA], 1994) links dysfunctions to the phases of the sexual response cycle: (i) desire (this phase includes desire to have sexual activity and sexual fantasies); (ii) excitement (this phase consists of a subjectively felt sense of sexual pleasure and related physiological changes, for example, penile erections and vaginal lubrication); (iii) orgasm (this phase consists of the climax or peaking of sexual pleasure, with release of sexual tension and the rhythmic contraction of the perineal muscles and reproductive organs; in the male there is also ejaculation of seminal fluid, and in the female contraction of the wall of the outer third of the vagina); and (iv) resolution (this phase consists of a sense of muscular relaxation and general well-being, in the male this also includes a physiologically refractory period in which further erection and orgasm do not take place).

The dysfunctions, linked to the first three of these phases, are classified below.

6.27.2.1 Sexual Desire Disorders

6.27.2.1.1 Hypoactive sexual desire disorder

Here, there is an absence or deficiency of sexual fantasies and desire for sexual activity. The terms "low libido" and "reduced libido" are also commonly used to refer to this.

6.27.2.1.2 Sexual aversion disorder

In this disorder, there is an aversion to, and avoidance of, genital sexual contact with a sexual partner. Often the aversion is focused on a particular aspect of sexual experience. There may also be anxiety, fear, or disgust.

6.27.2.2 Sexual Arousal Disorders

6.27.2.2.1 Female sexual arousal disorder

Here, there is a persistent inability to attain or maintain adequate vaginal lubrication and vaginal expansion in response to sexual excitement.

6.27.2.2.2 Male erectile disorder

In this condition, the main feature is the persistent or recurrent inability to attain or sustain an adequate penile erection. There is much variability in this. Some attain very strong erections without being able to sustain them, some have sustainable erections which are not strong enough for penetration. Loss of erection during thrusting is also reported by some.

6.27.2.3 Orgasmic Disorders

6.27.2.3.1 Female orgasmic disorder

This is also referred to as "inhibited female orgasm," "anorgasmia," and more rarely, "inorgasmia." The essential feature is the persistent delay in, or absence of, orgasm following a normal sexual excitement phase.

6.27.2.3.2 Male orgasmic disorder

Here, the male has difficulty in reaching orgasm following a normal sexual excitement phase, despite adequate stimulation. This condition has also been called "inhibited male orgasm." An earlier term, "retarded ejaculation" is problematic, as it focuses on ejaculation rather than orgasm. In some conditions a male can reach an orgasm without discharging any semen. The new term refers specifically to the orgasmic experience.

6.27.2.3.3 Premature ejaculation

Here, the essential feature is the persistent onset of orgasm with minimal sexual stimulation. Men with this problem reach an orgasm prior to, or just after, penetration, thus making any meaningful coital activity impossible. Attempts to define premature ejaculation by linking it to partner's orgasm (cf. Masters & Johnson, 1970) is problematic.

6.27.2.4 Sexual Pain Disorders

In addition the *DSM-IV* includes the following:

6.27.2.4.1 Dyspareunia

Here, there is genital pain associated with sexual intercourse. This is most commonly experienced during coitus, but it can also occur before or after coitus. It can happen in both men and women, but it appears from clinical settings that it is much more common in the latter (Bancroft, 1989; Renshaw, 1988).

6.27.2.4.2 Vaginismus

This consists of the persistent involuntary contraction of the muscles surrounding the outer third of the vagina when penetration is attempted. When severe, it makes penetration impossible.

Each of the above dysfunctions can be either *lifelong* or *acquired.* A lifelong dysfunction is said to exist when the problem has been present since the beginning of sexual functioning, for example, a man who has never had an erection as an adult. In the acquired type, the dysfunction develops only after a period of normal functioning.

Sexual dysfunctions are also categorized into *generalized* and *situational* types. In the former, the dysfunction occurs in all situations, and is not linked to certain types of partners, situations, or stimulation. In the latter, the dysfunction is limited to certain types of stimulation, situations, or partners. For example, a man may have an erectile difficulty when attempting sex with a partner, but not when masturbating.

It is also important to note that there can be comorbidity in sexual dysfunctions. The co-occurrence of erectile dysfunction and premature ejaculation is not uncommonly seen in clinics.

6.27.3 ETIOLOGICAL FACTORS

Sexual dysfunctions may be due to a variety of etiological factors, and clinicians usually look for organic and psychological factors. The state of knowledge with regard to organic factors is not easy to summarize, as different dysfunctions can have different etiologies. The most work has been done on male erectile disorder. Endocrine, vascular, and neurological systems have been seen as crucial for erectile functioning (Bancroft, 1997). Alcohol and other drugs of abuse, and certain prescribed medications, can also have a role to play. For female dysfunctions, hormonal factors are sometimes strongly implicated, as in sexual arousal disorder where decreases in estrogen can cause vaginal dryness. Such changes are not uncommon following menopause or ovariectomy. Local infections, presence of pelvic tumor, and pelvic inflammatory disease are among the factors that can be associated with dyspareunia. Psychological factors in the etiology of sexual dysfunctions have been extensively written about (e.g., Bancroft, 1989; de Silva, 1994a; Wincze & Carey, 1991). The role of anxiety, including "performance anxiety," is commonly found to be linked to erectile disorder, and indeed some other dysfunctions. Stresses of various kinds, depressed affect, anger, and relationship factors have been implicated. In women, lack of learning to relinquish control has been considered by some authors as an important variable (McConaghy, 1993). Cognitive factors, including attitudes and beliefs, both individual and cultural, are also seen as relevant (e.g., Baker, 1993; Bhugra & de Silva, 1993; Spence, 1991). The overall picture from many studies with inconsistent results clearly points in the direction of multifactoral etiology for sexual dysfunctions. Biological factors, and cultural and psychological factors in the individual and relationship domains, seem to determine the origins of sexual dysfunctions, as indeed they determine and influence sexual functioning in general. These issues are well reviewed in McConaghy (1993) and Wincze & Carey (1991) among others.

6.27.4 ASSESSMENT OF SEXUAL DYSFUNCTION

Assessment of sexual dysfunctions should be comprehensive, and cover in detail the presenting problem(s) and the relevant associated factors. While the principles of clinical assessment of sexual dysfunctions is in theory no different from the clinical assessment of other problems, in practice it is often a more challenging task. Since sex is a very private aspect of one's life, detailed and open discussion of it, however relevant clinically, can be difficult for the patient and the inexperienced therapist. Further, some of the usual methods of clinical assessment, such as direct observation by therapist and reports from independent observers, are not possible for obvious reasons. Some of these matters, and other general issues in the assessment of sexual dysfunction, are discussed in detail in the literature (e.g., Bancroft, 1989; Hawton, 1985; Wincze & Carey, 1991).

6.27.4.1 Aims of Assessment

The purpose of assessment is to obtain as clear a picture as possible of the problem(s) and factors that may be related to it, so that a good formulation can be arrived at. From the perspective of psychological therapy, one would want to gain information about the dysfunction in behavioral terms, also including relevant cognitive aspects. What happens in the actual sexual situation needs to be enquired about, and this is usually facilitated by focusing on the most recent attempt. Information about the behavior of both partners will be elicited, including their antecedents and consequences. Relevant past experiences, past partners, traumatic events, and so forth are part of the picture. A full behavioral analysis (e.g., Kanfer & Saslow, 1969) should be aimed for.

6.27.4.2 The Interview

6.27.4.2.1 Special problems

The main source of information in assessment is the clinical interview. In the case of sexual dysfunction assessment, there are special problems associated with it (cf. de Silva, 1994a; Wincze & Carey, 1991). These include the following:

(i) There may be embarrassment on the part of the patient. The therapist needs to be sensitive to the difficulties the patient may have in talking about intimate matters. Starting with more general questions may help build rapport. Acknowledging that talking about sexual matters could be difficult can also help.

(ii) The language must be simple and easy to understand. The jargon that comes easily to a professional is often unfamiliar to the patient. Every effort must be made to ensure that the patient understands the questions.

(iii) Precise details need to be obtained about the problem presenting, going beyond general descriptions such as "I don't seem to want it any more" or "I have lost interest." The therapist, however, needs to be patient in enquiring about details. Careful probing is often needed.

(iv) There should be an attitude of nonjudgmental acceptance with regard to the patient's behavior, likes, and dislikes. Even unintended display of disapproval or surprise may discourage the patient from giving relevant details.

(v) It is possible that patients may not be able to disclose some information in the initial assessment interview. This may be due to embarrassment, or due to the therapist being still unfamiliar to them. It is important to allow patients to give more information in later sessions.

6.27.4.2.2 Areas to enquire about

The areas to be covered in the interview include the following:

(i) The nature of the problem in as much detail as required to obtain a full picture of the difficulty and all its associated factors, including anxiety and situational variations; in men with impotence, particular enquiry should be made about whether early morning erections are present or not, as their presence usually helps to rule out the possibility that the problem is organic.

(ii) The history of the problem, its beginnings and course, and present sexual activities including masturbation.

(iii) The partner's reactions to the problem, both in the sexual situation and in general.

(iv) The patient's sexual knowledge, beliefs, and attitudes, including those determined by religion, culture, and subculture.

(v) The patient's sexual likes, dislikes, preferences, and fantasies.

(vi) Past sexual history including relevant early experiences, first experience of intercourse, and so on.

(vii) Psychiatric and medical factors, including drugs, alcohol, and so forth; current depression is particularly important to assess.

(viii) Menstrual history and relation of problem to the menstrual cycle.

(ix) Contraception and past pregnancies, and attitude to the possibility of conception.

(x) General relationship factors.

(xi) Background factors, such as job, income, accommodation, extended family and so on, which can be sources of stress.

(xii) Previous treatment, if any.

More details may be needed on some of the areas than on others in a given case, and this is a matter of clinical judgment as the interview proceeds. Needless to say, therapists must be prepared to vary their enquiry to suit each patient, as needed. Most clinicians rely on a history schedule or a general checklist of topics to enquire about as a matter of routine. Examples of such checklists are available in, among others, de Silva (1994a), Hawton (1985), and Spence (1991). In practice, while such detailed checklists are indeed useful, flexibility is needed in their use; such a list or schedule should serve as a general guide rather than as something to be rigidly adhered to.

6.27.4.2.3 Individual and couple interviews

One major issue in interviewing patients with sexual dysfunction is whether the partners—when a couple present themselves for help—should be interviewed together or not. Different viewpoints have been expressed about this (e.g., Bancroft, 1989; Masters & Johnston 1970; Wincze & Carey, 1991). In general, a good arrangement is to see the couple jointly to start with, and then to conduct assessment interviews separately. If two therapists are available, this may be done in parallel sessions; if not, more time should be spent with the partner with the presenting problem, followed by a briefer interview with the other partner.

It is important that individual interview sessions are undertaken in all cases. This provides an opportunity for each partner to give his or her version of the problem, and to discuss with the therapist relevant matters, including feelings about the partner, without inhibition. It also gives an opportunity for individuals to divulge information that might have been kept away from the partner, such as an extramarital relationship, or a particular aspect of the individual's past history.

6.27.4.2.4 Motivation and selection

Assessment of the motivation of the patient/couple for therapy is an important aspect of the interview, although this may not prove easy in a single interview except perhaps to identify those who are clearly unwilling to accept the treatment offered. As for suitability for therapy, an assessment comprising two interviews at most is usually sufficient to identify those who are clearly not likely to benefit from the therapy that can be offered. For example, presence of clear psychiatric illness will often require appropriate treatment of that condition first; serious marital difficulties may require referral to a specialist clinic, unless therapists feel competent to deal with this themselves; and, when physical factors are probably involved, investigations of these, and a physical examination, will need to be arranged prior to acceptance for therapy.

6.27.4.2.5 Physical examination and investigations

An important issue for the clinician dealing with sexual dysfunctions is that of whether or not a physical examination and/or investigations should be asked for. Nonmedical clinicians cannot always assume that the clients referred to them have been adequately screened for possible organic factors. Some clinicians take the view that all patients presenting with sexual dysfunction should routinely be examined physically (e.g., Kolodny, Masters, & Johnson, 1979; Spence, 1991). This is unnecessary, but it is essential to have the facilities to get this and relevant investigations done if required in a given case. Bancroft (1989) has given an extremely useful set of indications for physical examination. These are:

(i) complaints of pain or discomfort during sex;

(ii) recent history of ill-health or physical symptoms other than the sexual problem;

(iii) recent onset of loss of sex drive with no apparent cause;

(iv) when the patient believes that a physical cause is most likely, or is concerned about the genitalia (e.g., a man complaining that his penis is too small or bent, or a woman suspecting that there is something abnormal about her sexual organs);

(v) history of abnormal puberty or other endocrine disorder;

(vi) in men, being aged over 50; and

(vii) in women, being in the pre- or post-menopausal age group or having a history of marked menstrual irregularities or infertility.

Where appropriate, the medical practitioner carrying out the physical examination will also carry out, or arrange for, relevant laboratory investigations. Details of the common investigations may be found in several sources including Bancroft (1989), Hawton (1985), and Wincze & Carey (1991).

6.27.4.2.6 Questionnaires and inventories

Data obtained from the interview can profitably be supplemented by the use of questionnaires and inventories. These help to cover some important areas quickly, but more importantly they provide quantitative data that are particularly useful in assessing differences between before and after treatment.

Several useful instruments are available for the measurement of sexual experiences, attitudes, dysfunctions, and other related matters. Hoon, Wincze, and Hoon (1976a) provide an inventory (Sexual Arousability Index) for the assessment of female sexual arousal. Lo Piccolo and Steger (1974) have developed an inventory (Sexual Interaction Inventory) to assess sexual interaction and satisfaction of a couple. Lief and Reed (1972) provide a questionnaire to assess both sexual knowledge and sexual attitudes, while Wilson (1978) has produced a useful fantasy questionnaire, which measures fantasies, desires, and actual behaviours. The Derogatis Sexual Functioning Index (Derogatis & Melisaratos, 1979) is a wide-ranging scale of sexual functioning covering 10 domains (e.g., information, desire, attitudes). While its comprehensiveness is no doubt an asset, its prohibitive length (245 items) makes it somewhat unwieldy for routine clinical use. A brief measure for assessing erectile functioning, developed recently, is the International Index of Erectile Function (Rosen et al., 1997).

A relatively recent British development is the Golombok–Rust Inventory of Sexual Satisfaction (GRISS; Rust & Golombok, 1986). This 28-item questionnaire, intended for use with heterosexual couples or individuals with a current heterosexual relationship, yields an overall score, for men and women separately, of the quality of sexual functioning. In addition, the following subscores can also be obtained: erectile dysfunction, premature ejaculation, anorgasmia, vaginismus, infrequency, poor communication, dissatisfaction, nonsensuality, and avoidance. This instrument has good reliability, and is easy to use. In view of the multiplicity of scores it yields, the GRISS is an economical instrument that can be used routinely.

A parallel, and equally economical, instrument for the assessment of the quality of the overall relationship is the Golombok–Rust Inventory of Marital State (GRIMS; Rust, Bennun, Crowe, & Golombok, 1988). Other established marital questionnaires include the Locke–Wallace Marital Adjustment Scale (Locke & Wallace, 1959) and the Dyadic Adjustment Scale (Spanier, 1976). The recently developed Marriage and Relationship Questionnaire (Russell & Wells, 1993) is another useful instrument to be considered.

When depression is a relevant factor needing to be assessed, a standard depression inventory may be used for this purpose. The same applies to anxiety.

6.27.4.2.7 Subjective ratings

Self-rating scales may be used as part of an assessment of the major variables in question for a given patient. For example, anxiety in sex, desire, and sexual arousal may each be rated by the patient on a 0 to 100 scale indicating subjective estimates (cf. de Silva, 1994a). Patients usually find these simple scales easy to use. Equally simple are frequency charts, recording the frequency of target behaviors on a daily basis. A predesigned diary provided by the assessor/therapist, specifying the targets to be recorded, is an effective way of obtaining baseline data as well as of monitoring change. Conte (1986) and Spence (1991), among others, provide discussions of these.

6.27.4.2.8 Physiological measures

Physiological techniques have been used in the assessment of sexual function for many years, receiving impetus from the work of Masters and Johnson (1966, 1970). Measuring techniques are available for both male and female arousal. Penile plethysmography for the assessment of erection is widely used in research and can be used in clinical practice where needed and practicable (e.g., Wagner & Green, 1981; Wincze et al., 1988). The measure may be of either penile volume or penile circumference changes. Penile plethysmography has also been used to assess nocturnal erections in an attempt to distinguish psychogenic from organically caused impotence (Karacan, 1978). The injection of a chemical vasodilator, such as papaverine, into one of the corpora cavernosa of the penis, is also used in the assessment of erectile disorder. If the patient develops a full erection following the injection, severe vascular insufficiency can be excluded as a cause of the problems (Brindley, 1983; Wagner, 1993). As for female arousal, the best established method is the photoplethysmography technique (Hoon, Wincze, & Hoon, 1976b), in which vasocongestion in the vaginal walls is measured with the help of a probe. Detailed discussions of these, and other laboratory techniques, for the assessment of sexual problems are provided by Bancroft (1989), Meisler and Carey (1990), McConaghy (1993), and Schiavi (1992).

In a clinical setting, however, the use of physiological methods for routine assessment is not feasible. Also, the interpretation of their results in the clinical context is not always clear-cut (Bancroft, 1989; Conte, 1986).

6.27.5 FORMULATION

All the information gained from the different aspects of assessment need to be carefully integrated. This should lead to a case formulation, the equivalent of a working hypothesis (Carey, Flasher, Maisto, & Turkat, 1984; Hawton, 1985). A good formulation will include the following:

(i) a detailed description of the problem;

(ii) predisposing factors (e.g., cultural beliefs, history of diabetes, strict upbringing, childhood traumatic events);

(iii) precipitating or triggering factors (e.g., childbirth, physical illness, redundancy, bereavement, discovery of partner's adultery, failure while attempting sex in insecure circumstances);

(iv) perpetuating factors (e.g., anxiety about possible failure, ongoing marital conflict, continuing stress at work); and

(v) prognostic factors (e.g., good overall relationship and commitment of both to the marriage as good prognostic factors).

The formulation will provide a tentative explanation of the problem, and also establish a basis for treatment. The formulation is fed back to the patient or couple, and discussed. Revision of the formulation may follow this discussion.

6.27.6 TREATMENT OF SEXUAL DYSFUNCTION

6.27.6.1 Behavioral Sex Therapy

6.27.6.1.1 The behavioral approach

Historically, there have been several psychological approaches to sexual problems (de Silva, 1994b). However, the major approach since the 1960s has been the behavioral one. Behavioral sex therapy became established as the treatment of choice for these problems in the 1970s, and began to be practiced widely in various parts of the world (Gillan, 1987).

In the modern folklore of sex therapy, it is widely held that the basic techniques of behavioral sex therapy derive from the work of William Masters and Virginia Johnson (Masters & Johnson, 1970). It is certainly true that Masters and Johnson developed, established, and popularized a treatment package that has had a major impact. However, the roots of behavioral sex therapy can be traced to the work of Joseph Wolpe in South Africa. Wolpe is regarded as the pioneer of modern behavior therapy, his work from the late 1940s on the application of learning principles to the analysis and modification of behavioral problems culminating in his book *Psychotherapy by reciprocal inhibition* (Wolpe, 1958). While much of the work reported in this book related to phobias and other anxiety disorders, Wolpe also reported behavioral work on sexual dysfunctions. He recognized the crucial role of anxiety in sexual problems, and used anxiety reduction as a key element in the treatment of these problems. The principle of the couple undertaking cooperative therapy, the need to remove pressure to perform, and the use of a graded series of activities eventually leading up to the resumption of sexual intercourse, which are seen as three major elements of present-day sex therapy, were key aspects of Wolpe's approach.

Wolpe (1958) cites cases of both erectile dysfunction and premature ejaculation with whom he had successfully used this approach. It is perhaps worth quoting a passage that summarizes Wolpe's approach:

> The patient is told to inform his sexual partner (quoting the therapist if necessary) that his sexual difficulties are due to absurd but automatic fears in the sexual situation, and that he will overcome them if she will help him, i.e. if she will participate on a few occasions in situations of great sexual closeness without expecting intercourse or exerting pressure toward it. He is to ask her to be patient and affectionate and not to criticize. Assured of her cooperation, he is to lie in bed with her in the nude in a perfectly easy, relaxed way, and thereafter to do just what he really feels like doing *and no more*. He has no duty at any stage to reach any criterion of performance. It is found that from one love session to the next there is a decrease in anxiety and an increase in sexual excitation and therefore in the extent of the caresses to which the patient feels impelled. He has increasingly strong erections, and usually after a few sessions coitus is accomplished and then gradually improves. (Wolpe, 1958, p. 131)

6.27.6.1.2 Present-day conjoint cognitive-behavioral sex therapy

While the work of Wolpe (1958) represents the early use of standard behavior therapy techniques for sexual dysfunctions (see also Lazarus, 1963), it is profitable to consider these and other behavioral techniques as elements that may be incorporated into a wider treatment package. The obvious reason for this is that sexual problems are often multifaceted so that to deal with them effectively one needs several methods. The general package most widely used in this way is the conjoint therapy of Masters and Johnson (1970), modified and further developed by subsequent writers (e.g. Bancroft, 1989; Gillan, 1987; Hawton, 1985; Spence, 1991; Wincze & Carey, 1991). One major new development is the incorporation of cognitive principles and techniques (e.g. Baker, 1993; Spence, 1991). This approach may be termed "conjoint cognitive-behavioral sex therapy."

In the Masters and Johnson conjoint therapy approach, the presenting partner and spouse are seen as a couple for therapy. In the original program, each couple was seen by a male and female cotherapist team. Therapy was carried out on an intensive basis: daily sessions over a two-week period (Masters & Johnson, 1970). Other clinicians and researchers found that the involvement of a second therapist added little to the program and that sessions did not need to be so closely massed together (Arentewicz & Schmidt, 1983; Bancroft, 1989; Crowe, Gillan, & Golombok, 1982).

The main elements of the conjoint cognitive-behavioral sex therapy approach may be summarized as follows:

(i) Treating the dysfunction as a joint problem. This helps to reduce worry and guilt in the presenting partner and also emphasizes that the need is to learn, or relearn, how to have satisfactory sex jointly.

(ii) Reduction of anxiety. This is achieved by several strategies, including banning any attempt at intercourse. This removes the pressure to perform. Relaxation training may also be used as an extra help. Graded steps are recommended, so that progress is achieved without a resurgence of anxiety.

(iii) Setting sexual tasks or assignments to be carried out at home. They are specific behavioral tasks and involve touching, caressing, and so on. The two main stages of this are "nongenital sensate focus," where the touching excludes genitals and breasts, and "genital sensate focus" where these are included. These basic tasks aim to help the couple to learn giving and receiving pleasure by touch, with no pressure for performance, moving from less sexual to more intimate interactions.

(iv) Work on eliciting and changing negative or problematic cognitions.

(v) Educating the couple in sexual knowledge, for example, anatomy, physiology, coital positions.

(vi) Helping the couple to develop sexual and other communication skills.

(vii) Using specific additional techniques for specific dysfunctions.

While (i) to (vi) above are common to all, there are specific interventions designed to deal with specific presenting problems. The timing of their introduction is flexible; they are usually introduced after some progress has been made in the common stages.

This program is a cognitive-behavioral package in that there is no attempt to interpret the presenting symptoms in terms of psychodynamic constructs, and that behavioral tasks and cognitive work are a major part of the package. The degree to which an approach geared towards unraveling conflicts and problems in the overall relationship is incorporated into this, varies from therapist to therapist and from case to case (Beck, 1992; Crowe & Ridley, 1990; Woody, 1992). Anxiety reduction is a key part of this package. The prohibition of attempts at intercourse helps to achieve this, as immediately the performance anxiety in the male and fears of pain and so on in the female are removed. Other techniques of anxiety reduction may be added as required. McCarthy (1977, 1992), for example, has listed a number of ways, both general and specific, in which anxiety can be reduced in sexual problems.

The sensate focus assignments help a couple to learn to relax in each other's company and enjoy physical contact and interaction without worries of failure. In this relaxed, mutually pleasuring stage, they can acquire the confidence to move towards more intimate interactions. It is perhaps worth noting here that the progression from nongenital to genital sensate focus, and from there to more specific and more explicitly sexual acts, is similar in many ways to an *in vivo* desensitization program (Wolpe, 1958). Self-exploration may also be incorporated into the program where required. Communication, both verbal and nonverbal, on matters of pleasure, sensations, and sexual responses is encouraged and taught (e.g., how to indicate to the partner where and how to touch and how to express pleasure at what the partner is doing). The verbal aspects of this kind of simple, but to many couples new, interaction may be role-played and rehearsed during therapy sessions. The meetings with the therapist are crucial in discussing progress or otherwise of the homework assignments, and difficulties and problems are discussed fully. Not infrequently in these feedback discussions relevant new material about the relationship emerges for the first time (Bancroft, 1989; Hawton, 1985).

Cognitive therapy principles have a key part to play. The elicitation and modification of cognitions related to the dysfunction are the main feature of this, and individual work along these lines is often a key part of therapy. Where maladaptive cognitions have a role in the genesis and/or maintenance of a problem, these need to be challenged and changed. Common myths, attitudes, and idiosyncratic beliefs, and so forth, often contribute to sexual difficulties (Baker & de Silva, 1988; Bishay, 1988; de Silva & Dissanayake, 1989). Spence (1991) has provided a useful discussion of the use of cognitive strategies in the treatment of sexual difficulties. She includes fantasy training and attention-focusing skills as possible aspects of therapy. The major cognitive interventions, however, consist of identifying and restructuring the relevant cognitions. Maladaptive or negative thoughts need to be identified and changed as needed (Zilbergeld, 1978, 1992). This approach is well represented in the work of Baker (1993). She highlights the role of the individual's core assumptions about gender role and accompanying expected behaviors. Such assumptions are reflected in automatic thoughts, commonly reported by patients in sex therapy, such as: "My partner will leave me if I continue to lose my erections" or "I can't be very masculine if I don't last long with a partner." Baker (1993) argues that these negative thoughts play a crucial role in maintaining, and in some cases even causing, sexual dysfunctions. The cognitive approach she uses aims to challenge and modify these dysfunctional cognitions, and to break the vicious circle of negative thoughts that contribute to difficulties. The role of cognitive work has also been emphasized by Bancroft (1997) and Wincze and Carey (1991). The need to focus on the partner's cognitions as well as those of the presenting patient has also to be emphasized. Typical partner cognitions include: "I am no longer exciting to him," "He is just not trying," and "She must be having an affair with someone" (cf. Wincze & Carey, 1991).

Specific techniques are incorporated into this general program in the treatment of specific disorders. Comments on the treatment of some specific dysfunctions are made below.

(i) Hypoactive sexual desire disorder

Low interest usually begins to respond to the general treatment package if nothing more serious is underlying. Additional techniques are self-focusing, self-stimulation, use of vibrators, and stimulation with erotic material such as pictures, videos, and audiotapes. (Gillan, 1979, 1987). It is important, however, that the kind of erotic material recommended or provided is not distasteful to the patients, and so the choice is best left to them. Fantasy training is a related technique, sometimes useful for those whose fantasies are minimal (Spence, 1991). To encourage fantasies, published fantasy materials may be used, such as the volumes of fantasies published by Nancy Friday (1976, 1991). Masturbation training, usually with fantasy, may also be considered. The use of agreed timetables for sex are also found to be useful (e.g., Crowe & Ridley, 1990). The therapist would negotiate with the couple a timetable for sex; for example, intercourse will take place only on certain days of the week, or sex will be initiated by each partner on certain days only. This approach is often quite effective in cases where the partner with the low level of desire finds the demands made by the spouse too much, thus making the problem worse. The timetable helps to establish an acceptable pattern or schedule, within which further progress can be made.

(ii) Male erectile disorder

In the genital sensate focus stage, "teasing" is introduced, that is, periods of penile stimulation alternating with absence of stimulation. While erections may spontaneously occur, these are not considered the aim of therapy at this stage and the couple are encouraged to let the erection subside before restimulating. This helps in training them not to rush to intercourse once an erection is there, and also demonstrates that erections, when lost, can reappear. The next stage is vaginal entry, in the female superior position but with no movement. In the following stage the female makes slow movements, eventually leading to the male participating in and/or initiating movement, and using different positions.

Cognitive work has a particularly valuable role to play in the treatment of this disorder. Positive sexual thoughts should be identified and encouraged. The patient needs to be helped to refocus his thinking onto more positive cognitions. One way of doing this is to encourage recall of the thought content during past satisfactory sexual experiences. The therapist can also help the patient to develop positive thoughts by prompting "typical" helpful thoughts (Wincze & Carey, 1991). There is also a need to appraise and reappraise the meaning of specific types of sexual acts. Negative meanings or appraisals that inhibit the sexual functioning need to be altered (cf. Bancroft, 1997).

Some cognitive work may also be needed with the partner. Partners of men with erectile disorder not uncommonly develop negative cognitions, and they need to be dealt with.

(iii) Female orgasmic disorder

For females with orgasmic dysfunction the main additional element in the therapy package is a good deal of self-focusing and self-stimulation (Barbach, 1980; Gillan, 1987; Heiman & Lo Piccolo, 1988; Lo Piccolo & Stock, 1986). This helps the patient to learn to enjoy the sexual sensations in a relaxed manner. These self-sessions, including stimulation until orgasm is achieved, can be built into the basic program as parallel assignments. It has been shown that the use of vibrators can help these women to achieve orgasm; this may be done by the patient herself first, and the partner may help her to achieve orgasm with the vibrator in later stages. The use of fantasy and erotic materials may also be used as an adjunct (Gillan, 1979, 1987; Spence, 1991). Exercises to achieve control over the pubococcygeal muscle and to strengthen its tone, commonly referred to as "Kegel exercises" (Kegel, 1952), have also been recommended as an aid to achieving orgasm. For females who are unable to achieve orgasm with the partner but have no problem in masturbation, other elements may need to be added to the program. For example, orgasmic reconditioning may be attempted, in which the patient is taught to pair the positive pleasurable aspects of self-stimulation or other sexual situations with images of the partner in a fantasy-based graded program (Asirdas & Beech, 1975; Gillan, 1987).

In some, perhaps many, instances a woman's inability or difficulty in reaching an orgasm is linked to her inability to relinquish control (McConaghy, 1993, 1996). Some help specifically directed towards this, involving education, counseling and practice exercises, is necessary in such cases.

(iv) Male orgasmic disorder

The aim is to work towards intravaginal ejaculation, in a series of steps gradually approaching this goal. Again the instructions are introduced at the genital touching stage. For those males who do not reach an orgasm easily in any situation, vigorous stimulation ("superstimulation") with the aid of a lubricant is recommended. The use of a vibrator may also be considered. Once orgasm can be achieved in this way, vaginal entry, after some initial manual stimulation, may be attempted. In those men whose problem is that they cannot reach orgasm in the vagina but can do so with manual stimulation, a graded program in which orgasm is achieved by manual stimulation, with the penis increasingly close to the vagina, is recommended. In the next stage vaginal entry is achieved, after stimulation by hand close to orgasm. Even then, some manual stimulation may be needed to achieve orgasm once the penis is in the vagina. Suitable coital positions that facilitate these steps need to be recommended. Subsequently, vaginal stimulation alone will be sufficient for orgasm (Kaplan, 1987).

(v) Premature ejaculation

There are two, closely similar, techniques used for premature ejaculation. Masters and Johnson (1970) recommend what is called the "squeeze" technique. The couple are asked to practice this in the genital touching state. The female stimulates the penis of her partner with her hand, and when the man feels he is about to reach a climax, he indicates this to her with a prearranged signal. She then squeezes the penis hard for two or three seconds. For squeezing, the penis is held with the thumb on the frenulum and the first and second fingers on the opposite surface, one on each side of the coronal ridge. The squeeze makes the man lose his urge to ejaculate, and also perhaps some of the erection. This process of stimulation and squeeze is repeated several times in a session. Several sessions of this leads to gradual increase in ejaculatory control, and the couple is then asked to effect vaginal entry, in the woman-above position. At first, entry is not followed by movement. If the man feels he is about to ejaculate during vaginal containment, he communicates this to his partner who then lifts herself off him lightly and applies the squeeze. Kolodny et al. (1979) recommend a basilar squeeze technique at this stage so that the penis does not have to be completely disengaged. The penis is held at the base, anterior to posterior, and the pressure applied. The couple may eventually revert to preferred positions.

The squeeze technique is, in fact, a variant of the start–stop method described in 1956 by Semans, which is used by many therapists (e.g. Kaplan, 1974). This consists of stimulating the penis and stopping at the point of near-climax, and repeating the process several times. Initially, the stimulation is with a dry hand; later a lubricant is used to increase sensitivity and make the sensations more like the experience of vaginal entry (Gillan, 1987). The rest of the program consists of vaginal containment without movement, followed by movement in the woman-above position.

(vi) Vaginismus

This is treated by helping the patient, as a first step, to learn to relax and to explore her own genitals. Following this, a graded series of steps involving penetration using own fingers, and dilators (or trainers) of increasing sizes, is undertaken (Gillan, 1987; Scholl, 1988). The use of a vaginal lubricant may be advised. After the initial stages, the partner may be included in the procedure. This is done, however, with the patient retaining control. In many cases, this graduated dilation training leads to quick improvement.

6.27.6.1.3 Some general considerations on therapy

Some general points about this treatment approach need to be made.

(i) The therapy package

The package in its basic form is for use with all sexual dysfunctions, with the specific elements added to suit specific difficulties. There are, however, many instances where there is no need to apply the whole package, where perhaps sexual counseling and basic education are all that is needed (Bancroft, 1989; Hawton, 1985; Kaplan, 1987). The therapist needs to have a flexible approach in applying the therapy package or parts of it.

(ii) Psychogenic and organic problems

The program is intended mainly for psychogenic problems, as patients with clearly organic problems may need different forms of therapy. On the other hand, there is no reason why some aspects of the program should not be used even with those whose problems are not psychogenic, as a way of helping them to relax in their sexual activity and enhance their sexual experience, thus facilitating whatever physical treatment may be used. For example, in elderly men with erectile dysfunction who, due to aging and other physical causes, may not be able to have erectile function restored, much can still be achieved by a program aimed at enhancing their enjoyment of sexual activity, enabling them to accept that sex need not always mean vaginal intercourse (Gibson, 1992). It is also important to remember that the psychogenic–organic distinction is not always clear cut, and there are often multiple causal factors (Bhugra & Crowe, 1995). A problem caused, or triggered, by a physical condition, may often be aggravated or maintained by psychological factors, such as anxiety, invalidism, and diminished self-esteem. In many cases, substantial psychological help is needed in addition to a physical intervention.

(iii) Flexibility

The program is meant to be applied flexibly. The needs of each couple determine what changes to aim for, and the therapist must be prepared to change the direction of a program as and when required; for example, a couple presenting with a premature ejaculation problem may turn out to be one where the basic problem is lack of responsiveness in the female. Some couples require a good deal of direct education; shy patients may not be able to participate fully in therapy sessions until their embarrassment is overcome, and will need considerable time and effort to reach the point where therapy can proceed. The need for flexibility is very well illustrated by Lobitz, Lo Piccolo, Lobitz, and Brockway (1976) and Wincze and Carey (1991).

(iv) Resistance to the program

The program can sometimes meet with resistance. A couple may not carry out homework assignments, or do them only infrequently or cursorily. Their difficulties will need to be fully explored. Previously unacknowledged marital or relationship problems may come to the surface at this stage, in which case efforts should be directed towards resolving these (Bancroft, 1989; Crowe & Ridley, 1990).

(v) Additions to the program

Additions to the basic program need not be confined to the specific techniques mentioned above. Any suitable cognitive and/or behavioral technique for aspects of the problem may be incorporated as required. For example, when a strong phobic element is present, an intervention to deal with the phobia may be used; for a man whose dysfunction is bound up with paraphiliac desires, a parallel program aimed at dealing with these may be required (de Silva, 1995).

(vi) Functional analysis

The notion of functional analysis (Kanfer & Saslow, 1969) is extremely useful in devising individualized treatment programs. When the assessment shows clearly identifiable factors related to the problem behavior, the systematic manipulation of these can achieve impressive results, usually as part of the program, but sometimes also as the main intervention (Lobitz et al. 1976).

6.27.6.2 Some Practical Issues

As noted earlier, Masters and Johnson (1970) used male and female teams of cotherapists in their program, but others have shown that a second therapist adds little to the program effectiveness (e.g., Crowe et al., 1982). On the other hand, in certain cases an additional therapist of the opposite sex to the main therapist can be an advantage, for example, by making it easier for both of the partners to communicate about the problem and their feelings about it.

The individuals should be given an opportunity to report to the therapist separately, that is, in the absence of the partner, at least in some of the sessions. This enables the therapist to gain a balanced account of the progress and related matters.

Giving written instructions, with illustrations, is a valuable addition to the therapy program. They should be used as a supplement to verbal instructions. Equally useful is to recommend a well-written basic book on sex. There are many good books that may be recommended, for example, Barnes and Rodwell (1992), Delvin (1974) and Yaffe and Fenwick (1986a, 1986b). Films, videos, and slides may also be used (Gillan, 1987).

6.27.6.3 Therapy for Those Without Partners

When a patient comes for therapy without a partner, what help can be offered? If the patient has a steady partner who, though unwilling to come to the clinic, will co-operate with a therapy program, a "remote control" approach may be used, with the presenting partner also acting as communicator of instructions. The use of written material will be particularly useful in such cases. Clinical experience shows that this is a less than ideal substitute for conjoint therapy, but should be considered in the right circumstances. If the refusal of the partner to attend the clinic reflects a poor relationship, and/or an attitude that it is all the other's problem, then clearly the chances of joint work being successfully carried out are slim.

A somewhat different problem arises when the patient has no partner available. Many young men with erectile or ejaculatory problems not only do not have a steady partner but also avoid developing relationships, through fear of failure and rejection. Individual therapy is the only option available in such cases, unless group therapy is considered and facilities are available for it (see below).

The basic principles of individual sex therapy are largely the same as those for couples. Education, counseling, anxiety reduction in various ways including relaxation, self-focusing and self-stimulation, and fantasy training are all possible and useful elements in such programs. Cognitive principles have a key role. As for specific techniques, premature ejaculators will find the start-stop technique easier to use than the squeeze. Imaginal desensitization may be used for fear or anxiety, while role play and social skills training can be useful where required (McCarthy, 1992). The sexual reeducation program of Zilbergeld considers it important to dispel some widespread male "myths" about sex (such as that sex always means intercourse, that the male must always take the active role, and so on) in helping these persons, and exploration—and correction—of the individual's misconceptions about sex will be a useful element in an individual sex therapy program (Zilbergeld, 1978, 1992). For females, masturbatory exercises, Kegel exercises, fantasy training, vibrator use, and other such techniques that are possible for the individual to use without a partner, may be used as needed.

The treatment of individuals without partners presenting with sexual problems is discussed by, among others, Anson (1995) and Catalan, Hawton, and Day (1991).

The use of surrogate partners in the treatment of patients who come without partners has been reported and recommended by some therapists.

Several sex therapists in the USA use surrogate therapy (Dauw, 1988; Sommers, 1980), while in the UK Cole (1988) has described such therapy with 425 patients, 390 men and the rest women. Of these, 316 (74.4%) completed therapy; unfortunately, the follow-up was possible in only 13.3% of these. There are serious problems with the use of surrogate therapy, including obvious legal and ethical issues. For example, in the Cole sample, the spouse in many cases was not aware that the patient had come for therapy. A serious clinical question is whether patients who have been treated with a surrogate partner will be able to generalize their gains to other situations. In view of these reservations, it is difficult to recommend surrogate therapy as an option in the management of sexual dysfunction.

6.27.6.4 Group Therapy

In recent years, an increasing number of therapists have treated patients with sexual dysfunction in groups. There are reports in the literature of male groups, female groups, couple groups, and mixed-single groups; and there have been groups for patients with similar problems and groups for heterogeneous problems (e.g., Barbach & Flaherty, 1980; Kayata & Szydlo, 1988; O'Gorman, 1978; Spence, 1985; Zilbergeld, 1975). The groups have used a variety of techniques, including education, task-setting, relaxation, desensitization, instructions to use masturbation and vibrators, and open discussion of problems. Particularly for young and sexually diffident persons, the experience of well-conducted group therapy can be of much benefit (Bancroft, 1989).

6.27.6.5 Efficacy of Therapy

What about the efficacy of the therapeutic approaches and techniques that have been discussed above? The very high success rates reported by Masters and Johnson (1970; also Kolodny et al., 1979) have not been matched by later investigators but there is, generally, evidence that the conjoint cognitive-behavioral approach is beneficial to many patients (Arentewicz & Schmidt, 1983; Bancroft, 1989; Hawton, 1992; Hawton, Catalan, Martin, & Fagg, 1986; Spence, 1991). A thorough evaluation of sex therapy outcome is not easy to undertake because of various confounding factors: heterogeneity of samples, lack of uniformity in outcome measures, ambiguity of criteria of improvement, preponderance of single-case reports, poor description of patient characteristics, absence of data on drop-outs and failures, and so on (Beck, 1992). Within these limitations, the available data are encouraging. There are no reliable comparative outcome data, but on the whole 50–60% of couples who enter treatment show satisfactory outcome. Marked differences in outcome exist for specific sexual dysfunctions. For example, excellent results are obtained for vaginismus (e.g., Hawton & Catalan, 1990), whereas the treatment of hypoactive sexual desire appears to be less effective, especially in the long term (e.g., Hawton, Catalan, & Fagg, 1991). While the conjoint cognitive-behavioral therapy approach is the best option when it is feasible, it is up to clinicians to use their ingenuity and judgment in choosing, for each case, those elements of therapy that are particularly suitable for the problems they are called upon to deal with.

A related issue is that of the mechanisms of change. Even when various techniques and strategies achieve clinical success, the mechanisms through which change has been achieved is not always clear. Bancroft (1997) has recently highlighted this issue and offered a valuable, if brief, discussion. The relative lack of understanding of mechanisms of change also reflects the uncertainty about the etiological factors in these dysfunctions.

The outcome literature also points to factors associated with prognosis. Good prognostic factors include the quality of the overall relationship. Motivation for therapy also appears to be a key factor. There is also some evidence that the attractiveness of the partners to each other predicts satisfactory outcome. Current psychiatric illness is a predictor of poor outcome. These issues have been reviewed by Hawton (1992).

6.27.6.6 A Note on Physical Treatments

A brief note is necessary about physical treatment. A variety of physical interventions are used in medical settings for sexual dysfunctions. It is beyond the scope of this chapter to review these. Hormonal therapy, surgery, vacuum devices, and penile prosthetic devices have been used, and certain drugs have also been claimed to be of value. Much of this work has been reviewed by Bancroft (1989), Bhugra and Crowe (1995), McConaghy (1996) and others. In recent years, many reports have appeared on the use of injections of smooth muscle relaxants such as papaverine and prostaglandin E into one of the corpora cavernosa of the penis to induce erections (e.g. Brindley, 1986; Linet & Ogring, 1996). The erections induced in this way may last from one to four hours and are usually adequate for satisfactory intercourse. The patient is taught to give these injections himself, and the partner may also be taught to play this role. The use of this method to help men with organically caused erectile problems, or those who have failed to respond to an adequate trial of psychological methods, is advocated by several authorities. There is, however, an urgent need for further research and the use of this approach needs caution (Althof & Turner, 1992; Bhughra & Crowe, 1995; Crowe & Qureshi, 1991). The procedure also has some side-effects, especially parapism (prolonged erection) in a small number of cases. An even more recent development is the intraurethral administration of prostaglandin E (e.g., Wolfson, Pickett, Scott, De Kernion, & Rajfer, 1993).

When used appropriately after careful investigation, physical methods do have a useful role in the treatment of sexual dysfunctions. However, when the problem is largely psychologically determined, the use of physical treatments can be counterproductive. Even when there are physical causes of the presenting problem, and the main treatment is of a physical nature, additional psychological help along the lines discussed above is often useful and necessary (Wincze & Carey, 1991). The reliance on a physical treatment alone in the treatment of sexual dysfunction is not recommended (Bhugra & Crowe, 1995).

6.27.6.7 Scope of Cognitive-behavioral Sex Therapy

It was noted above that success rates have declined in recent years when compared to the very high rates reported in early years. This may be due to changes in culture and to changes in the nature of referrals for specialist help. Lo Piccolo (1994) has argued that the behavioral approach of the 1970s and the 1980s needs to be augmented, and that a "postmodern" sex therapy is required. In this approach, while the behavioral outlook is still the primary feature, the role that sexual dysfunctions may play in maintaining a systemic homeostasis for the couple in crucial areas of their relationship (e.g., intimacy, trust, power) is recognized, and is appropriately dealt with. Second, it is recognized that a sexual problem may have individual psychodynamic significance. Third, it is recognized that a sexual dysfunction may be a mechanism for the patient to deal with unresolved family or origin issues, such as problems of closeness associated with an alcoholic father, or an aversive reaction associated with incestuous abuse. Finally, the operant reinforcing value of a sexual dysfunction for clients in their larger environment is looked into; for example, "the financial success that comes to a man who works especially hard to compensate for his erectile failure" (Lo Piccolo, 1994, p. 6).

It is clear that all but one of these aspects of sexual dysfunction highlighted by Lo Piccolo (1994) can be accommodated easily within the broad framework of the cognitive-behavioral approach. In fact this happens almost routinely in actual clinical practice. As noted above, relationship factors are always an important area to investigate and work on in sex therapy. A systemic approach may be of much value in this endeavor in some cases. Such an approach can be accommodated easily within a broad cognitive-behavioral framework, as demonstrated by Crowe and Ridley (1990). The reinforcing value of the sexual problem would naturally be investigated and dealt with in the cognitive-behavioral approach, as indeed it is done for all behavioral difficulties (Kanfer & Saslow, 1969). The historical aspects of a case need to be considered in any approach, and a good cognitive-behavioral formulation would necessarily include recognition of these.

As for the psychodynamic value and significance of a symptom, this may appear at first sight to be an aspect that does not easily fit within a cognitive-behavioral framework. Kaplan (1974, 1987) has argued for the use of a psychodynamic approach if and when behavioral procedures produce no further change in a patient, in other words when there is resistance. However, it can be argued that a broadly conceived cognitive-behavioral approach, imaginatively applied, should be able to deal with these matters. It appears that what is needed in such cases is for the individual to be helped to reappraise the meanings of certain sexual acts or responses (Bancroft, 1997). Negative meanings acquired in childhood, persisting into adult life and inhibiting appropriate sexual responses, need to be reappraised. As Bancroft (1997) points out, there is no doubt that this endeavor "lends itself particularly well to the cognitive-behavioral approach" (p. 247). What is required is for the therapist to lead the patient towards this necessary reappraisal with the skillful and sensitive use of cognitive-behavioral principles.

6.27.7 TREATMENT ISSUES WITH SPECIAL POPULATIONS

Sexual dysfunctions occurring in various special populations need some consideration. The approach to treatment described in the above sections is a robust one, the principles of which are applicable to all groups. However, certain additional considerations are sometimes needed, and treatment needs to be adapted as required. A few commonly encountered special clinical populations are discussed below.

6.27.7.1 The Elderly

Elderly couples and individuals increasingly attend services for sexual problems (Gibson, 1992; Spence, 1991). This is not because of any real increase of sexual dysfunctions in the group, but because of the awareness of the availability of services and also the increasing acceptance that sexual activity in later life is not something to be ashamed of (Gibson, 1992). Erectile disorder is one of the commonest presentations (Mulligan, 1989); male and female orgasmic disorder also present for help. While physiological influences have a clear role to play in some of these cases, problems of ill-health can also contribute to, and/or complicate, the difficulties. Changing life circumstances, including the nature of the overall relationship between a couple, are also relevant factors. Psychological factors, especially attitudinal ones, may also play a part. It is not uncommon for elderly people to take the view that sexual activity should no longer be part of their lives, and this can be a problem when the partner continues to desire an active sex life.

In the treatment of elderly clients, all of the above need to be considered in the assessment, and should be part of the formulation. When needed, advice, information, and reassurance need to be given. The normality of continuing sex in later years may need to be emphasized. If there are fears or concerns about one's loss of attractiveness to the partner, some specific cognitive work on this will need to be undertaken.

The therapy program needs to take into account the clients' preferences and longstanding habits and practices, and any instructions for new and adventurous sexual activity should be given only after careful consideration and discussion. Greater emphasis on the nongenital aspects of sexual activity may be needed, and many elderly couples can learn to find much sexual pleasure in this way. Specific practical advice may include the use of lubricants, when there is a female arousal disorder including lack of lubrication—a very common presentation—and on how vaginal penetration may be achieved even with a not fully erect penis (Gillan, 1987). Finally, there are instances when the presentation of a sexual dysfunction in this age group is linked to anxiety about not being able to perform as well as in previous years. This is particularly so with males who may get concerned about their declining erectile response. Part of the treatment would then be providing information about the common changes in sexual functioning with increasing age, thus allaying any undue anxiety. The variability of the effects of aging on sex needs to be emphasized. Further, increasing the need for direct physical stimulation of the partner's penis in order to obtain an erection has to be emphasized, and the instructions for touching and foreplay need to include this as a major part.

6.27.7.2 Those with Physical Handicaps and Chronic Illnesses

Many clients with physical handicaps and chronic illnesses seek help for sexual problems. Cardiac problems, epilepsy, arthritis, cancer, and prostrate problems are among the difficulties that are commonly encountered. Assessment should include full details of the problems, including the study of medical reports about the client's difficulties. The medication the client may be on is also important to ascertain, as it may well have an effect on sexual functioning and the presenting dysfunction may even be just a secondary result of medication. A third area to pay attention to is how the physical illness or handicap has affected the person psychologically, mainly in the areas of self-image and role in relation to the partner. Chronic illness and handicaps often lead to invalidism, which affects the person's functioning including confidence and role in the area of sex. These issues need to be addressed in therapy, and it is best done using cognitive techniques with the individual and in joint counseling (cf. Malloy & Herold, 1986).

When there is chronic handicap, the aim of therapy for sexual dysfunction should be to maximize pleasurable sexual activity that is possible within the limits imposed by the handicap. A couple may need to use only certain coital positions, and variations within these. Those who are paraplegic or quadraplegic, or who have a limited range of motion due to back problems or arthritis, need education and advice on comfortable positions (cf. Bullard, 1988). Sometimes the focus needs to be on noncoital sexual activities. Couples may need to be given carefully graded behavioral homework exercises, in which they can proceed at a slow pace and without fear of pain or risk of fatigue. Some of these issues are discussed in detail by Schover (1992), Schover and Jensen (1988), and Spence (1991).

6.27.7.3 Gay Clients

Presentation of gay men for help in sexual dysfunction is common (Reece, 1988). The problems they present are varied, and cover the full spectrum that is seen in heterosexual men (Bhugra & Wright, 1995). Etiological factors often include fear of HIV/AIDS, uncertainty about sexual orientation, and feelings of being shunned or oppressed by society at large (cf. Bhugra, 1987; Dupras & Morriset, 1993). In the treatment of these clients, the general principles of cognitive-behavioral sex therapy are applied, with special focus on the issues noted above. Therapists need to be nonjudgmental in their attitude. When fear of sexually transmitted diseases are a part of the picture, clear advice on safe sex practices needs to be provided as part of the therapy package.

In the treatment of gay clients without partners, a group approach may be considered (cf. Reece, 1985). This format provides an economical and effective way of dealing with issues of stigma, ambivalence about sexual orientation and so on, in addition to work on specific dysfunctions. Another issue that needs to be dealt with, in the treatment of gay men without partners, is how one might get over the fear—and avoidance—of developing new relationships, out of embarrassment about the sexual dysfunction. Here, a behavioral rehearsal may be used to provide practice in disclosing the dysfunction to a new partner (cf. McCarthy, 1992).

6.27.7.4 Women with Eating Disorders

Females with eating disorders, especially anorexia nervosa, present a special challenge to therapists. There is a very high incidence of sexual problems in women with anorexia nervosa (Beaumont, Abraham, & Simson, 1981; Bancroft, 1989; de Silva & Todd, 1998; Raboch & Faltus, 1991). The reasons for this are complex. Clearly, in severe anorexia nervosa endocrine factors are involved, and this affects sexual functioning. There is also evidence that many anorexic patients have anxieties about sexuality and womanhood (cf. Anderson, 1985). When they seek treatment, it is often for hypoactive female sexual disorder, or for arousal disorder. Anorgasmia is also found as a problem, and not uncommonly sexual aversion disorder (see de Silva & Todd, 1998).

There are major issues in the treatment of these clients. While the basic cognitive-behavioral approach described in this chapter forms the basis of therapy for them, its application has to be cautious and carefully tailored to the individual. Often they come for treatment with some ambivalence; they may come either due to the need to please their partner if they are in a relationship, or in order to "become normal." Any attempt to treat sexual dysfunction while the client is still at a very low body weight is a mistake. The pace of therapy should be determined by the client's readiness. Preliminary work on sex education and attitudes may be needed (Van Vreckem & Vandereycken, 1994). Individual work preceding joint work is often advisable. Specific cognitive work on the significance of sex and sexuality, the client's self-concept, and so on may also be needed. Essentially, the therapy with this group of clients takes a slower, more finely graded form than in general sexual dysfunction therapy. Examples of the treatment of females with anorexia nervosa along these lines are found, among others, in Guile, Horne, and Dunston (1978) and de Silva and Todd (1998).

6.27.8 SUMMARY AND COMMENTS ON FUTURE DEVELOPMENTS

This chapter has reviewed the nature, diagnosis, etiology, assessment, and treatment of sexual dysfunction. The field has developed rapidly since the 1970s, with many practicing clinical psychologists getting actively involved in the clinical management of these problems, and in research aimed at elucidating them. Work in this area is now very much part of mainstream clinical psychology practice.

The current picture is, in essence, a promising one. There is much in the literature to guide the practitioner in the clinical assessment and treatment of these difficulties. The outcome literature is relatively weak, due to a variety of factors. However, there is enough in the literature on the outcome of therapy for sexual dysfunction to enable practitioners confidently to undertake the treatment of those patients who seek help for sexual problems.

As for the future, several developments can be predicted. Many therapists have begun to use and develop cognitive techniques more extensively in recent years, and this trend will continue to grow. The incorporation of the systemic approach into a broad cognitive-behavioral framework is another recent development that is likely to progress further. An integrated approach deriving concepts and strategies from the cognitive-behavioral and the systemic traditions may well emerge as the favored model in the near future. The other major area of development is likely to be in the physical treatments for sexual dysfunctions, mainly but not exclusively male erectile dysfunction. Extensive and ambitious research is currently taking place in this area, and the results of these investigations and trials are likely to have an impact on sexual dysfunction therapy. It is probable that more effective physical treatments will become available, but this is unlikely to reduce the need or demand for psychological treatments. First, the proportion of patients who will derive significant benefit from physical treatments is likely to be limited. Second, even when an effective physical treatment is used for a patient or couple, there will remain a clear need for additional psychological help. For these cases, it is likely that an integrated approach combining physical and psychological interventions will become the treatment of choice.

> Marriage is one of the most nearly universal of human institutions. No other touches so intimately the life of practically every member of the earth's population. (Terman, 1938, p.1)

6.28.1 INTRODUCTION

An overwhelming percentage of people become involved in intimate couple relationships at some point in their lives. In Western countries over 90% of the population marry by age 50 years (DeGuilbert-Lantione & Monnier, 1992; McDonald, 1995). Even among those who choose not to marry, the vast majority engage in "marriage-like" relationships by living together in committed, couple relationships (McDonald, 1995). Expectations of couple relationships are high. In Western cultures the vast majority of adults perceive their marital relationship as their primary source of support and affection (Levinger & Huston, 1990). Most young unmarried adults expect to marry at some point in their lives, for that marriage to be lifelong, and expect their partners to show sexual monogamy, honesty, expressions of affection, intimacy, and support (Millard, 1990).

Almost all couples that marry report high levels of relationship satisfaction early in their relationship (Markman & Hahlweg, 1993). Many couples sustain a mutually satisfying relationship, and seem to derive many benefits from that relationship. Relative to other people, those in satisfying marriages have lower rates of psychological distress, higher rated life happiness, and greater resistance to the detrimental effects of negative life events (Glenn & Weaver, 1981; Gore, 1978; Gove, Hughes, & Style, 1983; Halford, Kelly, & Markman, 1997). Unfortunately, for many other couples their relationship quality and satisfaction erodes over time. Relationship problems spill over to negatively affect partners' ability to cope with parenting and work outside the home, and this has major detrimental effects on them and their children (Halford & Markman, 1996; Sanders, Nicholson, & Floyd, 1997).

Seeking help about relationship problems is very common. Relationship preparation and enhancement programs are widely becoming accepted and attended by increasing proportions of the population entering marriage (Bradbury & Fincham, 1990; Stanley, Markman, Leber, & St. Peters, 1995; Simons, Harris, & Willis, 1994). In fact, relationship preparation programs are more widely attended than just about any other form of psychoeducational program (Simons et al., 1994). Couple relationship problems are one of the most common presenting problem of adults seeking psychological assistance (Veroff, Kulka, & Douvan, 1981), and couples often seek divorce mediation when their relationships end (Emery & Wyer, 1987; Walsh, Jacob, & Simons, 1995). In this chapter we analyze the nature and significance of relationship problems, assessment of couple relationships, the conduct of couples therapy, and prevention of relationship problems.

6.28.2 NATURE AND SIGNIFICANCE OF MARITAL DISTRESS

6.28.2.1 Prevalence of Marital Problems

The most statistically reliable index of marital distress is divorce rates, and divorce has reached epidemic proportions in most Western societies. About 45% of Australian marriages, 55% of American, 42% of UK, and 37% of German end in divorce (De Gulbert-Lantoine & Monnier, 1992; McDonald, 1995). As painful as the experience of divorce is for many people, most divorcees still aspire to be in a committed relationship. In the US about 75% of divorced people remarry within five years of the end of their first marriage (Glick, 1989; Martin & Bumpass, 1989). The divorce rates of second marriages are even higher than for first marriages (Glick, 1989).

Divorce rates represent only a portion of couples experiencing relationship problems. Many couples have significant relationship distress, but opt to stay together for various reasons such as the financial implications of divorce, and personal and cultural expectations about marriage (Gottman, 1993, 1994). Surveys of representative samples of married adults show that between 80% and 85% report they are very satisfied with their current relationship (Beach, Arias, & O'Leary, 1986; Eddy, Heyman, & Weiss, 1991, Gallup, 1989; Reynolds, Rizzo, Gallagher, & Speedy, 1979; Stanley & Markman, 1996). However, satisfied partners tend to make unrealistically positive comments and predictions about their relationship functioning (Fowers, Lyons, & Montel, 1996). For example, the majority of maritally satisfied partners believe there is zero probability that they will ever divorce, despite the well-publicized evidence of how common divorce is (Fowers et al., 1996)

Furthermore, of the married people who report high relationship satisfaction, 40% also report having seriously considered leaving their current partners at some point (Gallup Poll, 1989), and over 50% are characterized by interaction patterns that erode satisfaction and predict future divorce (Stanley & Markman, 1996). Thus, even those couples who report that they are very satisfied in their relationship at any point in time are at risk for future problems and divorce. All these figures converge on the point that significant relationship problems are common in most Western societies.

6.28.2.2 Effects of Relationship Problems

Given the central importance placed upon couple relationships, it is not surprising to find that relationship distress and dissolution are experienced as extremely stressful events. In fact, after a death in the immediate family, marital distress and divorce are rated as the most severe of commonly occurring stresses experienced by adults (Bloom, Asher, & White, 1978). Relationship distress is associated with increased risk for development of a range of individual psychological disorders including depression, particularly in women (Bebbington, 1987; Coyne, Kahn, & Gotlib, 1987; Hooley, Orleay, & Teasdale, 1986), alcohol abuse, particularly in men (O'Farrell, 1989), and anxiety disorders (Craske & Zoellner, 1995), and sexual dysfunction in both sexes (Zimmer, 1983). Marital conflict is also associated with increased behavior problems and poorer psychological adjustment in the couples' children (Emery, 1982; Emery, Joyce, & Fincham, 1987; Grych & Fincham, 1990).

The causal connections between marital distress and individual psychological disorder are complex. Long-standing, psychological disorders reduce the chance of having a satisfactory marriage. For example, patients diagnosed with schizophrenia or severe personality disorders are much less likely than the rest of the population to get married, and are much more likely to get divorced if they do marry (Lange, Schaap, & van Widenfelt, 1993; Reich & Thompson, 1985). However, the association between marital problems and psychiatric disorder is not simply psychological disorder causing marital problems. For example, in cases of coexisting marital problems and depression, the marital problems often antedate the onset of depression (Birchnall & Kennard, 1983). Even when treatment produces an improvement in depressed mood there is limited effect on marital distress (Dobson, 1987; Klerman & Weissman, 1982; O'Leary & Beach, 1990), and the ongoing marital problems are associated with poor prognosis for the depression (Rousanville, Weissman, Prusoff, & Herceg-Baron, 1979). Similarly, marital problems stimulate excessive drinking (Davis, Berenson, Steinglass, & Davis, 1974), precipitate relapse by people with high alcohol dependence who have been abstinent from alcohol consumption (Maisto, O'Farrell, Connors, McKay, & Pelcovits, 1988), and are predictive of poor prognosis in alcohol treatment programs (Billings & Moos, 1983; Vannicelli, Gingereich, & Ryback, 1983). Thus, a simple unidirectional model of causality is inadequate. Marital distress and psychological disorder reciprocally influence each other.

In addition to the psychological maladjustment associated with relationship problems, relationship problems are also correlated with poorer physical health. Individuals in satisfying and supportive marriages are less likely to have major illness, and they recover better when they do become ill than individuals in distressed relationships (Burman & Margolin, 1992; Schmaling & Sher, 1997). The mechanisms linking poor physical health to relationship problems are complex and only partially understood. Relationship distress has some indirect effects mediated through health-related behaviors, such as low adherence to medical treatment regimens by those in distressed relationships (Schmaling & Sher, 1997).

Inadvertent reinforcement of illness behavior in distressed marriages and inadequate support of coping in chronic illness can have a negative impact upon partners' health (Schmaling & Sher, 1997). There are also some direct effects of relationship distress on physiological processes which impact upon health. For example, relationship conflict is associated with immunosuppression (Kiecolt-Glaser et al., 1993), elevated stress hormone levels (Keicolt-Glaser et al., 1996), elevated blood pressure in people with essential hypertension (Ewart, Taylor, Kraemer, & Agras, 1991), and possibly atherosclerosis (Gottman, 1990; Medalie & Goldbourt, 1976). Each of these physiological effects are likely to increase risk for serious health problems.

Relationship problems at home spill over to work. More specifically, for men relationship conflict at home is associated with days lost at work and poor work performance (Thompson, 1997). The economic cost of the effects of relationship problems are extensive.

Relationship violence has a major effect on the health and well-being of many partners in committed relationships. About 25% of all marriages have at least one episode of interspousal physical aggression at some point (O'Leary et al., 1989; Strauss, Gelles, & Steinmetz, 1980), and this violence almost always is associated with relationship distress. Over half of maritally distressed couples presenting for therapy report having experienced interpartner violence in the previous year (O'Leary & Vivian, 1990). Whilst men and women are equally likely to engage in aggressive acts such as hitting, pushing, or slapping (Strauss & Gelles, 1986; O'Leary et al., 1989), men are much more likely to engage in severe violence, and women are at particular risk for being injured or even killed by their partner (Koop, 1985; Stets & Strauss, 1990). Even when physical injuries are less severe, violence can have severe negative consequences for female victims. Women repeatedly assaulted by their partners are at high risk of developing depression, alcohol abuse, psychosomatic disorders, and are high users of the healthcare system (Cascardi, Langhinrichsen, & Vivian, 1992; Jaffee, Wolfe, Wilson, & Zak, 1986; Stets & Strauss, 1990). Relationship aggression is also linked to child abuse (Grych & Fincham, 1990), development of antisocial behavior in male offspring (Grych & Fincham, 1990), and increased risk of children entering a violent relationship as an adult (Widom, 1989).

6.28.3 NATURE AND ETIOLOGY OF RELATIONSHIP PROBLEMS

The common element to clinical presentations of relationship problems is almost always dissatisfaction by at least one partner with the relationship. Attempts to define and measure relationship problems have taken relationship (marital) satisfaction, as assessed by self-report inventories, as the ultimate criterion (Weiss & Heyman, 1997). The most widely used self-report inventories are the Locke–Wallace Marital Adjustment Test (Locke & Wallace, 1959), and an expanded revision known as the Dyadic Adjustment Scale (Spanier, 1976). These two scales, and many similar scales, have been subjected to repeated criticism (e.g., Heyman, Sayers, & Bellack, 1994) for confounding relationship satisfaction, measured by items such as "overall how would you rate your marital happiness," with adjustment processes alleged to influence satisfaction, measured by items such as "how often do you and your partner disagree about finances?" While the collapsing of the constructs of relationship satisfaction and adjustment seems conceptually unsound, factor analyses of measures of marital adjustment and dissatisfaction consistently show that partners make unidimensional, global evaluations of their relationship problems (Eddy, Heyman, & Weiss, 1991; Heyman et al., 1994). In essence, partners who are dissatisfied with their relationships tend to report that just about anything that could be negative about their relationship is negative.

The finding that reported relationship distress seems to reflect an overriding global evaluation of negative aspects of the relationship does not mean that relationship quality is unidimensional. In the late 1990s work shows that couples distinguish between dissatisfaction about negative aspects of the relationship (e.g., the level of distress associated with conflict) and satisfaction with positive aspects of the relationship (e.g., the sense of satisfaction with expressions of love) (Fincham, Beach, & Kemp-Fincham, 1997). Some couples present with severe relationship distress and little positive feeling about their partner or the relationship, while other couples are distressed by the negative aspects of the relationship associated with dissatisfaction but still retain some positive feelings about the partner. The latter group of couples seem to benefit more from couples therapy (Hahlweg, Schindler, Revenstorf, & Brengelman, 1984). In either group of couples their initial focus often is on reducing negative behaviors associated with dissatisfaction, but successful therapy also needs to prompt couples to attend to developing positive aspects of the relationship.

Active consideration of separation is common in couples with relationship problems, (Weiss & Cerreto, 1980). However, the association of relationship problems, consideration of separation, and divorce is not straightforward. Most couples who eventually divorce go through a protracted process which proceeds from worsening relationship problems, through active consideration of separation, to actual separation, and eventually to divorce (Gottman, 1990, 1993). Often in couple presentations one or both partners are ambivalent about the relationship and its future. Ambivalence can be a major challenge to the partners. They risk neither proceeding with separation nor working to improve a distressed relationship, and by default the distress of the status quo is maintained. The systematic assessment of relationship problem areas and strengths, combined with conjoint goal setting, often serves to overcome this inertia (Halford, Osgarby, & Kelly, 1996; Weiss & Halford, 1995). We will say more on this in the section on relationship assessment (Section 6.28.5.2).

6.28.4 BEHAVIORAL, COGNITIVE, AND AFFECTIVE COMPONENTS OF RELATIONSHIP PROBLEMS

Problems in communication are the most frequently cited specific complaint by couples seeking therapy, with up to 90% of distressed couples citing these difficulties as a major issue in the relationship (Bornstein & Bornstein, 1986). Both independent observers and spouses report communication deficiencies are associated with relationship distress (Weiss & Heyman, 1997). When discussing problem issues, distressed partners are often hostile, and criticise and demand change of each other (Christensen & Shenk, 1991; Gottman & Krokoff, 1989; Gottman, 1994; Halford, Hahlweg, & Dunne, 1990; Heavey, Christensen, & Malmuth, 1995; Notarius & Markman, 1993). Distressed couples also do not actively listen to their partner when discussing problems (Halford et al., 1990; Jacobson, McDonald, Follette, & Berley, 1985; Weiss & Heyman, 1990), and tend to withdraw from problem discussions (Christensen & Shenk, 1991; Gottman, 1994; Gottman & Krokoff, 1989; Halford, Gravestock, Lowe, & Scheldt, 1992; Heavey, Christensen, & Malmuth, 1995). Contentious relationship issues are less likely to be resolved by discussion in distressed couples than non-distressed couples (Halford et al., 1992).

Distressed couples are highly reactive at an emotional level to their partners' behavior, and show significantly higher rates of negative reciprocity during interaction than nondistressed couples (e.g., Gottman, Notarius, & Markman, 1977; Schaap, 1984). In observational studies of communication, the conditional probabilities of distressed partners responding negatively to their partner's negativity is much higher than the conditional probabilities for nondistressed partners (e.g., Halford et al., 1990). In addition to this negative reciprocity, relationship distress is also associated with high levels of psychophysiological arousal during interaction (e.g., Gottman & Levenson, 1988). This arousal is aversive, which may explain the higher rates of withdrawal during problem-focused discussions by maritally distressed partners (Christensen & Shenk, 1991; Gottman & Krokoff, 1989). In any case, both the extent of arousal and the frequency of withdrawal prospectively predict deterioration in marital satisfaction (Gottman, 1993; Gottman & Krokoff, 1989; Heavey, Layne, & Christensen, 1993; Heavey et al., 1995).

Another common complaint of couples seeking relationship therapy is the negativity of their day-to-day interactions (Halford, in press). Using behavioral checklists in which partners monitor their spouses' behavior there is a well-replicated finding that monitored daily behaviors correlate with relationship satisfaction (Birchler, Weiss, & Vincent, 1975; Halford & Sanders, 1988; Jacobson, Follette, & McDonald, 1982; Johnson & O'Leary, 1996). More specifically, relative to maritally satisfied couples, distressed couples report higher rates of negative, displeasing behaviors by their spouse and fewer positive, pleasing behaviors (Birchler et al., 1975; Halford & Sanders, 1988; Jacobson et al., 1982; Johnson & O'Leary, 1996). Furthermore, distressed couples tend to reciprocate on a *quid pro quo* basis the behaviors of their spouse. In other words, in a distressed relationship partners tend only to be positive if their partner recently has been positive, and if one partner behaves negatively the other often responds negatively immediately (Birchler et al., 1975; Jacobson et al., 1982). In contrast, satisfied couples' behavior is less contingent on the preceding partners' behaviors; satisfied couples tend to be positive irrespective of their partners' prior actions.

There also is evidence that distressed couples' perceptions of their partners' behavior are negatively biased. Distressed couples disagree to a greater extent with both objective observers (Robinson & Price, 1980) and with each other (Christensen & Nies, 1980; Jacobson & Moore, 1981) regarding the occurrence of particular behaviors in their relationship. More specifically, they tend to overestimate the frequency of negative partner behaviors. The nature of relationship distress cannot be understood simply in terms of the behaviors occurring during marital interaction, but also requires attention to the cognitive appraisal by partners of that interaction.

Distressed couple have a number of characteristic cognitions about their relationships (Beaucom, Epstein, Sayers, & Sher, 1989). Maritally distressed couples selectively attend to their partner's negative behavior (Eidelson & Epstein, 1982; Floyd & Markman, 1983; Jacobson & Moore, 1981), and selectively recall such negative behavior (Halford & Osgarby, 1996). In contrast, maritally, satisfied partners tend to overlook negative behaviors by their spouses (Gottman et al., 1977; Notarius, Benson, Sloane, Vanzetti, & Horyak, 1989), to have an unrealistically positive view of their partners and relationships (Fowers, Applegate, Olson, & Pomerantz, 1994), and to selectively recall positive aspects of relationship interaction (Halford & Osgarby, 1996).

Another characteristic of distressed couples in the cognitive domain is holding unrealistic beliefs about relationships and partners. More specifically, relative to happy couples, distressed couples are more likely to believe that any form of disagreement is destructive, that change by partners is not possible, and that rigid adherence to traditional gender roles is desirable (Baucom & Epstein, 1990; Eidelson & Epstein, 1982). Distressed couples also report that their relationships often violate standards about how they think their relationship should be (Baucon et al., 1996). For example, distressed women report that their partners do not share power within the relationship in the manner the women believe they should, and men believe their partners should invest more time and energy in the relationship than they do (Baucom et al., 1996).

Distressed couples attribute the causes of relationship problems to stable, internal, negative, and blameworthy characteristics of the partners (Bradbury & Fincham, 1990; Fincham & Bradbury, 1992). For example, a partner arriving home late from work may be perceived as "a generally selfish person who doesn't care about the family" by a maritally distressed partner. The same behavior may be attributed by a maritally satisfied partner as the spouse "struggling to keep up with a heavy load at work, and being subject to lots of pressure from the boss." The process of attributing much or all of the relationship problems to their partners leaves most people with relationship distress feeling powerless to improve their relationship (Vanzetti, Notarius, & NeeSmith, 1992). A key element of couples therapy is to enhance each partners' sense of relational efficacy or capacity to improve their relationship through their own actions (Halford, Sanders, & Behrens, 1994).

One additional cognitive characteristic of a distressed couple is that they expect negative outcomes from interaction with their partners. Distressed couples report that prior to a discussion they expect not to be able to resolve problem issues in their relationships (Vanzetti et al., 1992). In anticipation of a problem-solving discussion, maritally distressed partners show high physiological arousal (Gottman, 1994), negative affect, and become primed to access negative evaluative judgements about their partner and the relationship (Fincham, Garnier, Gano-Phillips, & Osborne, 1995).

The cognitive characteristics of distressed couples mediate their subsequent behavior toward their partners. For example, the occurrence of negative attributions is associated with subsequent behavioral negativity (Bradbury & Fincham, 1992). In unhappy couples, negative thoughts about the partner predict future negative behaviors better than predictions from previous behavior (Halford & Sanders, 1990), suggesting these cognitions are more than just the consequences of negative marital behavior. In other words, relationally distressed partners seem to respond to their subjective perceptions and memories of relationship interactions, and these perceptions and memories are negatively biased.

6.28.4.1 The Etiology of Relationship Distress

There are over 100 published studies assessing the longitudinal course of couple relationship satisfaction and stability (Karney & Bradbury, 1995). This comprehensive literature can be usefully summarized in terms of three broad classes of variables which impact upon the etiology of relationship problems: adaptive processes within the couple system, stressful events impinging upon the couple system, and enduring individual vulnerabilities of the partners (Bradbury, 1995).

Adaptive processes refer to the cognitive, behavioral, and affective processes that occur during couple interaction. Certain deficits in these adaptive processes seem to predispose couples to relationship problems. More specifically, deficits in communication and management of negative affect and conflict observed in engaged couples prospectively predict divorce and relationship dissatisfaction over the first 10 years of marriage (Markman & Hahlweg, 1993). Dysfunctional communication and negative affect regulation in engaged couples also predicts the development of relationship verbal and physical aggression in the first few years of marriage (Murphy & O'Leary, 1989; O'Leary et al., 1989), at least for mild to moderate severity aggression. Relationship aggression is often established early in the relationship, and usually continues and escalates once established (Murphy & O'Leary, 1989; O'Leary et al., 1989).

It is noteworthy that the communication and conflict management deficits observed in some engaged couples do not correlate with their reported relationship satisfaction or commitment at the time (Markman & Hahlweg, 1993; Sanders, Halford, & Behrens, 1996). It seems that these communication difficulties do not stop couples from forming committed relationships, but the difficulties do predispose couples to develop relationship problems later. In couples who have been married for some time, these same communication difficulties predict deterioration in relationship satisfaction and decreased relationship stability (Gottman, 1993, 1994)

The beliefs and expectations individuals have when entering into relationships and marriage predict the risk of divorce in the first few years of marriage (Olson & Fowers, 1986; Olson & Larsen, 1989). Couples characterized by unrealistic expectations and beliefs in areas such as importance of communication, appropriate methods of conflict resolution, importance of family and friends, and gender roles, have higher rates of erosion in relationship satisfaction than couples not so characterized. Negative attributional patterns in which partners attribute blame for relationship problems to stable, negative characteristics of their spouse also prospectively predict deterioration in relationship satisfaction (Fincham & Bradbury, 1990). Thus, certain communication and cognitive characteristics of the couple's adaptive processes predate, and prospectively predict, relationship problems.

Stressful events refer to the developmental transitions and acute and chronic circumstances which impinge upon the couple or individual partners. Relationship problems are more likely to develop during periods of high rates of change and stressful events (Karney & Bradbury, 1995). For example, the early stages of marriage, including transition to parenthood, is often associated with decline in couple relationship satisfaction (Cowen & Cowen, 1992), as is an increase in work demands (Thompson, 1997). Retirement is another major transition for couples which can be associated with relationship distress (Dickson, 1997). One partner developing a major health problem also puts couples at increased risk for relationship and sexual problems (Schmaling & Sher, 1997).

A common stressful transition worthy of special mention is entering a second marriage. Second marriages in which there are dependant children from an earlier relationship break down at very high rates (Booth & Edwards, 1992; Martin & Bumpass, 1989). Negotiating parenting roles in step-families is a common source of interpartner conflict, and unresolved differences in this area are the most common stated reason for relationship breakdown in step-families (Lawson & Sanders, 1994). Moreover remarital partners tend to repeat the same patterns of negative interactions with their new partners despite efforts to the contrary (Prado & Markman, in press).

In general, couples with less robust adaptive processes are believed to be particularly vulnerable to the negative effects of a range of stressful events (Markman, Halford, & Cordova, 1997). In particular, couples who lack communication skills, or who have inflexible or unrealistic expectations of relationships, find it hard negotiate the changes required to adapt to major life transitions (Markman, Stanley, & Blumberg, 1994). For example, one of us (WKH) is studying couples where the women were recently diagnosed with breast or gynecological cancer. In couples with good communication and effective mutual support the adversity of cancer diagnosis and treatment seems to bring the couples closer together and reinforce the relationship bonds. In contrast, couples with poor adaptive processes show deterioration in their relationships and poor individual coping with the cancer.

Enduring vulnerabilities refer to the stable historical, personal, and experiential factors which each partner brings to a relationship (Bradbury, 1995). Family of origin experiences have been widely studied as historical factors which correlate with risk of relationship problems. For example, the adult offspring of divorce are more likely than the rest of the population to divorce (Glenn & Kramer, 1987), and interparental aggression is associated with increased risk for having an aggressive relationship as an adult (Widom, 1989). The mechanisms by which exposure to parental divorce or aggression may impact upon subsequent adult relationships is becoming clearer. Exposure to parental divorce is associated with more negative expectations of marriage (Black & Sprenkle; 1991; Gibardi & Rosen, 1991; Van Widenfelt, Schaap, & Hosman, 1996), and with observable deficits in communication and conflict management in couples prior to marriage (Halford et al., 1994). Adult offpsring of parents who were aggressive also show deficits in communication, and conflict management skills in dating and marital relationships (Sanders, Halford, & Behrens, 1998; Skuja & Halford, 1998). Negative expectations and communication deficits may well be learned from the parents' relationships and subsequently these learned behaviors impact negatively upon the adult relationships of the offspring. The argument that communication difficulties may be acquired through observation and interaction with parents is supported by a finding from Howes and Markman (1991). They found couple communication style assessed premaritally predicted subsequent communication style when the partners become parents and were interacting with their children (Howes & Markman, 1991).

The association between personality variables and relationship problems has been widely studied. Normal personality variations do not seem to contribute much variance to relationship satisfaction (Gottman, 1994; Karney & Bradbury, 1995; Notarius & Markman, 1993). One exception is that low ability to regulate negative affect (high neuroticism) consistently has been found to predict higher risk for relationship problems and divorce (Karney & Bradbury, 1995). How this personality characteristic may impact upon relationship problems is not yet understood.

Another major risk indicator for relationship distress and divorce is past or present history of psychological disorder. Higher rates of relationship problems and divorce consistently have been reported in populations with severe psychiatric disorder (Halford, 1995), and in people with depression, alcohol abuse, and some anxiety disorders (Emmelkamp, De Haan, & Hoogduin, 1990; Halford, Kelly, Bouma, & Young, in press; Halford & Osgarby, 1993; O'Farrell & Birchler, 1987; Reich & Thompson, 1985; Ruscher & Gotlib, 1988; Weissman, 1987). As described earlier in this chapter, relationship problems and individual problems can both exacerbate each other (Halford et al., in press). In addition, certain personal vulnerabilties may dispose people to both psychological disorders and relationship problems. For example, deficits in interpersonal communication and negative affect regulation are risk factors that predict the onset of both alcohol abuse (Block, Block, & Keyes, 1988) and relationship problems (Markman & Hahlweg, 1993). This common risk factor might be part of the explanation for the common co-occurrence of relationship and alcohol problems.

6.28.5 COUPLES THERAPY

Intervention with relationship problems can potentially target couples' adaptive processes, stressful events, or enduring vulnerabilities, as each of these classes of variables influence relationship problems. The focus of all interventions evaluated in research has been on modifying couples' adaptive processes, either through conjoint therapy for couples with existing relationship problems (e.g., Baucom & Epstein, 1990; Halford, in press), or through brief programs to prevent the development of relationship problems (Halford & Behrens, 1996; Markman & Hahlweg, 1993). Often interventions are adapted to take account of the enduring vulnerabilities of the partners. For example, there has been considerable research on therapy with couples in which one partner has depression (Beach, Sandeen, & O'Leary, 1992) or alcohol abuse (O'Farrell & Rotunda, 1997). In the 1990s some work has focused on developing couples' adaptive processes to manage particular life transitions and stressful events, such as being in a step-family (Lawton & Sanders, 1994). In the rest of this chapter we focus on interventions targeting change in couple adaptive processes.

6.28.5.1 The Different Approaches to Couples Therapy

A number of different approaches to couples therapy, including behavioral, cognitive, cognitive-behavioral, emotion-focused, and insight-oriented couples therapy, have been demonstrated to improve the relationship satisfaction of the majority of couples who present for therapy (Baucom & Epstein, 1990; Greenberg & Johnson, 1988; Hahlweg & Markman, 1988; Halford, Sanders, & Behrens, 1993; Shadish et al., 1993; Snyder, Wills, & Grady-Fletcher, 1991a). All these approaches share the characteristics of the use of systematic assessment and goal setting at the beginning of therapy, and a focus on conjoint therapy targeting changes in the couples' adaptive processes.

The different theoretical approaches to couples therapy which have empirically validated efficacy have placed different emphases on the processes alleged to produce change in couples' adaptive processes. In insight-oriented and emotion-focused couples therapy emphasis was placed on changing partners' subjective experience of relationship interactions, usually through insights gained into the subjective significance of particular relationship events (Greenberg & Johnson, 1988; Snyder, Wills, & Grady-Fletcher, 1991b). In contrast, in behavioral approaches to couples therapy the original emphasis was on changing relationship interaction through procedures such as behavioral contracting and skills training in areas such as communication and problem-solving (Jacobson & Margolin, 1979). Cognitive behavioral couples therapy combined attempts to change the subjective experience of relationship interactions through cognitive change procedures and attempts to change relationship interactions with behavioral procedures (e.g., Baucom & Epstein, 1990; Halford et al., 1993).

The distinctions between these different empirically validated approaches to couples therapy are becoming somewhat blurred. Treatment manuals written for insight-oriented couples therapy (Snyder & Wills, 1989) include considerable use of behaviour change procedures that seem identical to those used in cognitive-behavioral couples therapy (Jacobson, 1991; Markman, 1991). Treatment manuals published by cognitive-behavioral couples therapists (Christensen, Jacobson, & Babcock, 1995; Weiss & Halford, 1995) describe the limitations of relying on changing relationship interactions and incorporate procedures acknowledged as very similar to those advocated by emotion-focused therapists to change the subjective experience of relationship interactions.

While there is some blurring of the distinctions between different theoretical approaches to couples therapy, there are still some important differences in such approaches. The most widely used approaches to couples therapy in clinical practice are systemic and strategic approaches (Boughner, Hayes, Bubenezer, & West, 1994), and there are a diversity of procedures used within these approaches (Fraenkel, 1997). There is little evidence by which to judge how useful these procedures are. In contrast, relatively few practitioners use the most extensively researched approach to couples therapy: cognitive-behavioral couples therapy (CBCT) (Markman, Halford, & Cordova, 1997; Shadish et al. 1993). As we believe in practice being guided by research, the couples-therapy approach outlined in this chapter is based on the CBCT approach, which has developed from the research foundation we reviewed earlier in this chapter.

6.28.5.2 Assessment of Relationship Problems and the Process of Couples Therapy

Clinical descriptions of cognitive-behavioral couples therapy emphasize the importance of developing therapeutic alliances with each partner, developing a shared understanding of relationship problems and goals which promotes adaptive change, and explicit negotiation with couples about their roles in therapy (e.g., Beach, Sandeen, & O'Leary, 1990; Baucom & Epstein, 1990; Christensen et al., 1995; Weiss & Halford, 1995). Assessment is crucial in achievement of these process outcomes in couples therapy. In essence, the therapist seeks through assessment both to establish an empathic understanding of each partner's experience of the relationship and to promote a shared conceptualization of problems in terms of relationship interactions. The shared conceptualization is the basis for the participants to negotiate the goals of therapy and to determine how those goals are to be achieved.

Establishing a shared conceptualization of relationship problems sometimes is a difficult therapeutic task. Therapists tend to see relationship problems in terms of the adaptive processes occurring between the partners. In contrast, couples often enter therapy conceptualizing their relationship problems as due to stable, global negative characteristics of their partners (Fincham & Bradbury, 1990), and believe there is little they can do individually to improve their relationship.

To achieve a shared, productive relationship focus in couples therapy the therapist initially assesses the presenting concerns from the perspective of each partner. Often these initial descriptions by clients are critical and blaming of the partner (e.g., "he does not communicate," "she is too demanding"). The therapist then uses a variety of strategies to promote a relationship focus. For example, strategic use of questioning can promote attention to relationship interaction (e.g., "How do you two resolve conflict?" "As a couple how do you ensure you have quality time together?"). Particular assessment tasks also prompt attention to relationship interaction. For example, undertaking certain communication tasks can be used to identify strengths and weaknesses in communication. Reframing summaries also can foster a relationship focus. For example, suppose a couple argue about parenting. One partner may present this issue as "he is too soft on the children when they misbehave." The spouse might describe the issue as "she is too harsh in her discipline of the children." The therapist may summarize this as: "as a couple you struggle to agree on the best ways to manage your children's behavior." The therapist's summary reframes the issue as a relationship challenge the couple can work on together.

In CBCT there is a strategic separation of assessment and therapy. At the completion of assessment the therapist provides the couple with structured feedback on the results of the assessment. This feedback summarizes and integrates the assessment information and focuses the results on how the problems can be conceptualized within a relationship framework. The process typically involves the therapist presenting the results of the assessment to the couple, one assessment instrument at a time. The therapist continually checks that the descriptions and conclusions being reached are accurate according to each partner. After presenting all the key findings the therapist summarizes the results and discusses with the couple possible goals for therapy. The most commonly identified goals are improving communication, controlling conflict, enhancing quality time together, and renegotiating key relationship responsibilities. Other common goals include working together to improve parenting difficulties, enhancing support for each other, and enhancing the expression of intimacy and closeness.

After developing a shared relationship focus, the next step in couples therapy is to have each partner define what she or he can do to change problematic interactions. This emphasis on self-change (also known as self-regulation) focuses therapy on that which each client has the most direct control over, namely their own behavior (Halford, Sanders, & Behrens, 1994). This is not to say that changes in the partner are unimportant, but rather that the most productive method of achieving change is for each partner to focus on their own opportunities to change.

For some couples the process of assessment, plus one or two sessions focused on self-directed goal setting and change, can be sufficient to improve a distressed relationship (Halford et al., 1996). For other couples, assessment is just the beginning of a more extensive therapeutic process, but serves the crucial function of determining the directions for therapy.

Assessment provides two kinds of information: content and process. Content information refers to the reports of the concerns of the partners, such as the specific content of conflicts, or their current thinking or actions about separation. Process information samples how the couple respond to the various probes or tasks the therapist initiates. For example, if the couple are asked to discuss an issue of relevance to the relationship, the therapist may be particularly interested in either the process of interchange between the partners (e.g., the degree of effective listening to each other's perspective) or the actual content of the discussion.

Many therapists rely exclusively on conjoint interviews with the couple to assess the content of relationship problems (Boughner, Hayes, Bubenezer, & West, 1994). This is a mistake. Content information obtained from conjoint interviews is less reliable than information derived from either individual interviews or self-report inventories (Haynes, Jensen, Wise, & Sherman, 1981). For example, physical abuse is dramatically under-reported in conjoint interviews relative to either self-report inventories or individual interviews (O'Leary, Vivian, & Malone, 1992). Furthermore, encouraging couples to recount lengthy lists of complaints about their partners in the presence of the partner rarely promotes a collaborative set to move therapy forward. Consequently, we recommend that a combination of self-report inventories and individual interviews be used to assess content information, and that conjoint interviews be focused on assessment of process.

A structure for an initial interview which illustrates the combination of process and content assessment is outlined in Table 1. The session begins with a brief conjoint interview in which the agenda for the session is negotiated. At the beginning the therapist should ask the couple an open-ended question about the reasons they are seeking assistance. When posing the question it is often helpful for the therapist to get eye contact with both partners, and then look at a point midway between the partners as the question is finished. The goal at this point is to establish if the couple can collaborate and conjointly tell a coherent story about their relationship problems. If each partner allows the other to speak, and there is mutual respect, then a conjoint intake interview may be possible. More commonly, in couples with relationship problems, the response to this initial probe is escalating conflict in the session, with each partner being blaming and negative toward the other. The therapist should intervene promptly to stop such escalation. The therapist also needs to note that the couple need to develop a mutually acceptable way of talking about their problems if therapy is to proceed successfully.

Table 1 Structure of couples initial interview.

Initial orientation (10 minutes)
  Introduction
  Present structure of session
  Ask for a brief/joint statement of problem

Individual interviews (30 minutes each)
  Current status of relationship
  Sources of difficulty
  Specific areas:
    behavior changes for self/partner
    communication
    time use
    sex
    external stressors
    individual problems
    domestic violence
    separation
    commitment

Joint session (20 minutes)
  Review individual material
  Describe behavioral couples therapy approach
  Review suitability of behavioral couples therapy
  Logistics of therapy

The second phase of the intake interview is then done with each individual partner, covering the key areas identified in Table 1. The goal in this phase is to identify key areas of concern, and to establish an empathic relationship with each partner. The third phase brings the couple back together again. In the third phase the therapist summarizes the key concerns identified by each partner. These summaries need to express the concerns in a manner consistent with the experience of each partner, and in a manner that allows mutual agreement that particular areas need attention. For example, the therapist might describe areas of disagreement as identified areas requiring further negotiation. Both partners can agree these are issues that they need to resolve.

Table 2 is a summary of key areas of relationship problems which need assessment, and some useful assessment instruments for each of those areas. The process of assessment typically involves each partner completing the various self-report inventories and behavioral monitoring tasks between therapy sessions. The therapist reviews and discusses the information each partner provides. In addition, the therapist often sets the couple particular tasks within sessions. A common assessment procedure is to have couples undertake one or more communication tasks, such as discussing a source of disagreement within the relationship. This is best done with the therapist outside the room observing via one-way screen or videorecording where available. The goal is to assess how the couple communicate and manage conflict. Further detail on these assessment tasks are available in O'Leary (1977), Baucom and Epstein (1990), and Halford (in press).

The assessment process is more than just passive collection of information. In the process of assessment the therapist is working with the partners to develop an agreed on concept of the relationship problems which facilitates change. The completion of assessment tasks often prompts each partner to consider aspects of their relationship in new ways. For example, as noted earlier, many partners in distressed relationships attribute the causes of their relationship problems to their partner, and feel powerless to change the things that distress them. In a version of the Areas of Change Questionnaire (Weiss & Halford, 1995), each partner is asked to identify behaviors they personally need to change to enhance their relationship. Just posing the question of self-change in a structured way can help the person to generate change ideas. Similarly, the experience of a communication assessment task can prompt partners to identify aspects of their own communication behavior they wish to change.

Table 2 Key areas of assessment for couples therapy.

Area	*Example measure*	*Explanation*
Relationship satisfaction	Dyadic Adjustment Scale (Spanier, 1976): 31-item self-report inventory	Level of distress, global evaluations of relationship
Divorce potential	Marital Status Inventory (Weiss & Ceretto, 1980); a 14-item rating scale	Steps toward separation, high steps predict poor prognosis
Behavior exchange	Areas of Change Questionnaire (Weiss & Perry, 1983); 34 items rating extent of requested behavior change by a partner	Current patterns of daily interaction, identify behavior change preferences of each client
Communication and conflict management		The most common presenting concern, and a key area requiring attention in much couples therapy
Aggression and violence	Conflict Tactics Scale (Strauss, 1979)	Verbal, psychological, and physical aggression between partners
Relationship standards and beliefs	Baucom et al. (1996)	The expectations partners have of each other and relationships. Often unrealistic beliefs can be a source of relationship problems

The assessment process needs to move couples stuck in a partner-blaming focus for distress to a relationship focused view of the problems. Ultimately the goal is to have each partner take responsibility for self-directing personal change to enhance the relationship (Halford et al., 1994).

6.28.5.3 Cognitive-behavioral Couples Therapy

Based upon the premise that a relationship is defined by the exchange of behaviors between partners, CBCT began as the application of behavioral contracting to the treatment of relationship problems. Couples were trained to monitor their partners' behavior and, based on such assessments, contingency contracts were developed to reduce displeasing and increase pleasing behaviors within the relationship (e.g., Azrin, Naster, & Jones, 1973; Stuart, 1969; Weiss, Hops, & Patterson, 1973). Such contracting initially stressed tightly structured *quid pro quo* agreements, in which spouses were taught systematically and immediately to reward desired behavior from the partner (Azrin et al., 1973; Stuart, 1969). This was later replaced by unilateral "good faith" contracts in which partners were asked to undertake positive change for the good of the relationship (e.g., Gottman, Notarius, Markman, & Gonso, 1976; Weiss, Birchler, & Vincent, 1974). Subsequently, emphasis has been placed on each partner actively seeking out information in order to self-select and implement self-change goals to enhance the relationship (Halford et al., 1994; Weiss & Halford, 1995). Although the details of the procedures have been refined, an emphasis on changing relationship behaviors remains an important element of how CBCT attempts to alter couples' adaptive processes.

In Table 3 some of the key behaviors identified as promoting long-term satisfying relationships are identified. In couples therapy partners are helped to self-identify behaviors that they wish to change within these different domains to enhance their intimacy with their partner. There are several ways of doing this. For example, partners can be asked to self-monitor behaviors within a given class and then to identify behaviors they wish to increase in that domain. A second example is the Caring Days Exercise (Weiss & Halford, 1995). In this procedure each person is encouraged to identify some small specific behaviors which they can do which demonstrate caring for their partner. To enhance their ability to self-select appropriate caring behaviors, partners can be assisted to be more creative in generating ideas. For example, to enhance creativity people can brainstorm ideas, they can ask their partner what would demonstrate caring effectively to them, they can ask friends about caring behaviors that they engage in within their relationships, they can observe others demonstrating caring in their normal day-to-day lives, or they can read through checklists of ideas and suggestions provided by the therapist. The self-regulatory focus encourages each person to take individual responsibility for being creative in identifying behaviors that they will engage in and to set themselves tasks of implementing behavioral changes.

A second element of CBCT is communication and problem-solving skills training. These skills are conceptualized as providing couples with the means to enhance intimate communication and resolve their current and future sources of conflict (Jacobson & Margolin, 1979; Notarius & Markman, 1994). In most applications of CBCT the communication skills targeted in training have been identified by the therapist based upon contrasting the couple's current communication with a model of adaptive marital communication. The models of adaptive marital communication were derived, in large part, from research contrasting the communication behaviors of maritally distressed and nondistressed couples in problem-solving interactions within research laboratories (see Weiss & Heyman, 1990, 1997, for reviews of this literature). Often CBCT would teach couples a relatively fixed curriculum of skills (e.g., paraphrasing, asking open-ended questions, behavioral pin-pointing), based on the assumption that each of these skills were adaptive as communication skills.

Research shows that there is no clear relationship between the use of particular, specific communication behaviors (e.g, paraphrasing, minimal encouragers) and relationship problems (Halford et al., 1990, 1993). Rather, it seems that there are a few broad classes of adaptive relationship communication behaviors, such as validation (active, positive listening to partner) and positive engagement, and use of any of a wide variety of behaviors within these broad classes is associated with improvements in relationship problems (Sayers, Baucom, Sher, Weiss, & Heyman, 1991). The specific behaviors within the broad classes which are functional vary across relationships, time and settings (Halford, Gravestock, Lowe, & Scheldt, 1991). In other words, different communication styles suit different relationships and circumstances, but we can be reasonably confident that an adaptive communication style will need to involve validation and positive engagement. Furthermore, successful couples do not always use these skills after intervention, but do so when needed (Hahlweg & Markman, 1996).

A crucial skill in couple interaction is management of negative affect. In successful long-term relationships, partners must both be able to manage their own negative feelings and respond constructively to their partner's negative feelings (Markman, Stanley, & Blumberg, 1944). One negative interaction erodes the effect of 5–10 previous positive interactions (Notarius & Markman, 1994), so preventing destructive negativity is crucial.

Table 3 Classes of behavior most strongly related to marital satisfaction.

Class of behavior	*Examples*
Affection	Saying "I love you" Giving a hug or kiss Enjoying a shared laugh or joke Saying they enjoy partner's company
Respect	Listening to the partner's opinion Telling partner of admiration/respect Showing confidence in partner's abilities Introducing partner to others with pride
Support	Doing errands for partner Making self available to do work for partner Asking partner about their day Doing something to save partner time/energy
Communication of ideas	Telling partner about their day Discussing topical events Giving an opinion Talking about mutual interest(s)
Shared quality time	Spending an hour or more just talking Work together on a project Take a drive or walk Go out together, just the two of you Discuss personal feelings

Applying the self-regulation approach to communication skills, each partner is assisted to self-select goals for changing his or her own communication, and to self-evaluate his or her own communication. For example, clients review their own couples discussions (e.g., an audiotape of a conversation at home on a difficult topic) with the therapist in sessions, with partners each focusing on their own communication. This maintains the therapeutic focus on what the client can change (i.e., his or her own behavior). Based on the assumption that adaptive marital communication is defined by its functional impact within the relationship, self-directed attempts at changes in communication are seen as behavioral experiments. Consequently, when a partner makes a change in communication that produces a negative outcome (e.g., making an assertive rather than aggressive request for change by the partner when discussing a particular issue elicits verbal abuse from the spouse), this shows that assertion was not adaptive in this context, and a different approach is needed.

A third element of CBCT is altering subjective experience of relationship interaction. Although CBCT always included recognition of the importance of internal mediators of external experience (Weiss, 1984), more recent developments have placed greater emphasis on cognitive and affective change strategies. Many of these strategies apply standard cognitive therapy procedures to relationship problems. For example, self-instructional strategies are used to modify negative attributions (Baucom & Lester, 1986) or control anger (Schindler & Vollmer, 1984), and guided discovery, Socratic dialogue and behavioral experiments are used to challenge irrational relationship beliefs (Baucom & Epstein, 1990; Halford, in press).

The greater emphasis on changing subjective experience in CBCT is particularly evident in recent changes in managing destructive conflict within distressed couples. Earlier versions of CBCT emphasized teaching communication and problem-solving skills to reduce conflict. More recently, emphasis has been placed on exploring with each partner the attributions, meaning, and significance attached to the issues which are sources of conflict (e.g., Christensen et al., 1995; Weiss & Halford, 1995). While there are variations in the details of the therapeutic process used by different authors, the common emphasis is on altering how partners respond to behaviors of their spouses which they dislike. Christensen et al. (1995) describe the goal of this process as promoting acceptance, which they define behaviorally as the reduction of attempts to get the other person to change. In essence, there is an attempt to balance a combination of behavior change to alter relationship interaction and change in the subjective experience of existing relationship interactions.

The CBCT approach to relationship dissatisfaction usefully can be summarized within an extension of the self-regulation framework proposed by Halford et al. (1994). Subjective dissatisfaction with your relationship can be responded to in one of five ways. First, you can alter the ways in which you attempt to persuade your partner to change, so that you get change. Second, you can alter your own behavior to enhance relationship functioning. These first two options were the focus of traditional behavioral couples therapy, producing behavior change through procedures such as behavioral contracting and negotiation. Third, you can alter your own subjective response to negative aspects of relationship interactions so that those aspects are less stressful and you feel no pressing need for change. This is what Christensen et al. (1995) call acceptance. Fourth, you can decide that particular existing behaviors are unacceptable, intolerable, and unchangeable, and that you will therefore leave the relationship. Finally, you can do nothing, and maintain the status quo. In our experience few clients have explored all these options for individual action.

6.28.5.4 The Effectiveness of Cognitive-behavioral Couples Therapy

CBCT consistently has been shown to be superior to no treatment or therapist contact control conditions in reducing marital distress (Hahlweg & Markman, 1988; Markman & Hahlweg, 1993). More specifically, CBCT improves couples' communication skills, reduces destructive conflict, enhances positivity of day-to-day interactions, and increases the positivity of couples' cognitions about their partners and their relationships (Hahlweg & Markman, 1988; Halford et al., 1993). In other words, CBCT is effective in changing the key identified risk factors for marital distress.

Among couples who present for couples therapy, the negative effects of relationship distress usually are already evident (Bloom, 1985). For example, alcohol abuse and depression are common in partners seeking marital therapy, as are behavior problems in the couples' children (Halford, Kelly, & Markman, 1997). These individual problems often result from the prolonged effects of marital distress, and make marital therapy less effective (Halford & Bouma, 1997). Furthermore, patterns of dysfunctional marital interaction typically become entrenched over time and resistant to change (Markman, Floyd, Stanley, & Storaasli, 1988; Raush, Barry, Hertel, & Swain, 1974). Eventually there is erosion of any positive affect toward the spouse, which is predictive of very poor response to couples therapy (Hahlweg, Schindler, Revenstorf, & Brengelmann, 1984). Approximately 25–30% of couples show no measurable improvement with CBCT, and as many as a further 30% improve somewhat from therapy but still remain significantly maritally distressed after treatment (Bray & Jouriles, 1995; Halford et al., 1993; Jacobson, 1989; Jacobson et al., 1984). Even among those couples who initially respond well to CBCT, there is substantial relapse toward marital distress over the next few years (Jacobson, Schmaling, & Holtzworth-Munroe, 1987; Snyder, Mangrum, & Wills, 1993; Snyder et al., 1991a). The consistent finding is that the longer couples have been maritally distressed, and the more severe their relationship dissatisfaction, the poorer their response to marital therapy (Whisman & Snyder, 1997).

The effectiveness of CBCT relative to other approaches to couples therapy is unclear. There are relatively few studies which compare approaches to couples therapy (Snyder et al., 1991a). One study compared insight-oriented and behavioral marital therapies. The findings were that each treatment was effective, with few significant differences in effects of the treatments in the short term (Snyder & Wills, 1989). At four-year follow-up the insight-oriented therapy was associated with lower rates of divorce and higher rated marital satisfaction than the behavioral marital therapy (Snyder et al., 1991a). However, this study has been the source of considerable controversy (Jacobson, 1991; Snyder et al., 1991b). A major criticism of the study was that the so-called insight-oriented therapy was not really psychodynamic in approach, but rather represented state of the art CBCT (Jacobson, 1991).

An important index of the value of couples therapy is the satisfaction of clients with the service they receive in that therapy. The magazine *Consumer Reports*, which is very widely read in the US, has its readers complete a survey every year. In one survey they asked about satisfaction with psychotherapy, including couples therapy. The results were very positive in terms of the effects of psychotherapy from the consumers' point of view. However, consumers expressed less satisfaction with couples' counseling than any other form of therapy. From one perspective, this makes the field of couples' counseling look ineffective. However, when one thinks about the goals of couples therapy, it actually makes sense that there will be less satisfaction from the consumers' point of view. Often one or sometimes both partners in couples therapy are using the therapy as a way of exiting the relationship—leaving the hurt spouse on the therapist's doorstep. Some marital therapists describe how a spouse who is interested in leaving the relationship often brings in the other spouse with the hope that the therapist will help wean the more committed spouse from the marriage and ease the break-up of the relationship.

In a survey of therapists conducted with practitioners in Colorado in the US (Stanley, Lobitz, & Markman, 1989), couples' therapists were asked to indicate the percentage of couples who were significantly improved or not improved, how many of the couples seen in the practice were still together, and how many decided to end their relationship. The results indicated that about 33% of the relationships ended in separation or divorce. Interestingly, the therapists rated 80% of these relationships that ended in divorce as a successful outcome. The *Consumer Reports* survey suggests that this 80% probably did not rate the therapy as a success from their own perspective (Seligman, 1995). Consumer satisfaction with couples therapy may be low because people unrealistically expect therapy to persuade their partners to stay with them.

6.28.5.5 Couples Therapy and Psychological Disorder

Couples therapy can be useful in the treatment of individual psychological disorders, either as the entire treatment or as an adjunct to individual treatment. More specifically, there have been a number of studies evaluating couples therapy and its effects on depression and alcohol abuse. In this section we evaluate this evidence.

As noted previously, people with co-existing marital problems and depression often do not respond well to traditional individual therapies for depression. Beach and O'Leary (1986) and Jacobson, Dabson, Fruzetti, Schmaling, and Salusky (1991) showed that CBCT was effective in reducing both marital distress and depression where wives were depressed and the couples were maritally distressed. Individual cognitive therapy also was somewhat effective with these clients, but not as effective as CBCT (Beach & O'Leary, 1986; Jacobson et al., 1991). Of particular interest was Jacobson's finding that, while both CBCT and cognitive therapy were helpful, adding cognitive therapy to CBCT did not enhance outcome. In Jacobson's study the treatment conditions were matched for total hours of therapy contact. As a consequence the combined condition got less CBCT than the

CBCT alone condition, and this may explain why the combined treatment condition did not do as well.

The Jacobson et al. (1991) study highlights that couples therapy should not be used for all presentation for depression by married clients. For depressed clients where there was no marital distress, individual cognitive therapy was superior to couples therapy in its effect on depression. Even when relationship problems and depression coexist there is a need to make careful judgments as to when couples therapy is most helpful. In couples where the individual depression is severe, the marital problems postdated the onset of depression, and neither partner attributes the cause of the depression to the marital problems, then marital therapy seems less effective than individual therapy (Jacobson et al., 1991). On the other hand, where the marital problems antedate the depression, the marital problems are severe, and the source of the depression is attributed by at least one of the partners to the marital problems, then marital therapy seems to be the treatment of choice (Jacobson et al., 1991).

There is a large body of literature attesting to the value of various forms of couples therapy in the treatment of alcohol problems. The best established approach is the use of CBCT to complement individual therapy in the treatment of alcohol abuse. In the case of people with heavy dependence on alcohol, there has been successful use of conjoint contracting to promote use of antebuse (an oral drug which induces severe illness if alcohol is consumed) to establish abstinence (O'Farrell & Bayog, 1986). Once sobriety is established, conjoint couples therapy when used in combination with ongoing use of antabuse promotes both improvements in relationship satisfaction and enhanced maintenance of drinking control (O'Farrell, Cutter, Choquette, Floyd, & Bayog, 1992; O'Farrell, Cutter, & Floyd, 1985). When CBCT is combined with relapse prevention training, there is even better maintenance of reduced alcohol consumption (O'Farrell, Choquette, Cutter, Brown, & McCourt, 1993). Furthermore, there is also a substantial reduction in the prevalence of marital violence after CBCT, at least in those couples with mild to moderate severity of violence (O'Farrell & Murphy, 1995).

There are two significant limitations on the evidence of the impact of couples treatments for problem drinking. First, all successful trials have used antabuse, and the effectiveness of CBCT without antabuse is unclear. Second, up to 50% of men in alcohol treatment refuse offers of couples-based treatment (O'Farrell, Kleinke, Thompson, & Cutter, 1986). This may be associated with more general reluctance of many people who abuse alcohol to accept treatment. Partners of male problem drinkers often present to treatment agencies reporting that their partners refuse to seek treatment (Halford & Osgarby, 1993). The frequent unwillingness of the person abusing alcohol to accept help, with consequent strains on the relationship and individual distress, have prompted the development of therapies to assist the spouses of heavy drinkers. For example, Sisson and Azrin (1986) and Thomas and Ager (1993) both developed therapies aiming to help clients reduce the negative impacts of their partner's drinking. Both these programs were aimed at teaching women to manage stress associated with their husbands' drinking and to encourage the men to seek individual therapy (Sisson & Azrin, 1986; Thomas & Ager, 1993). These programs do assist the women to reduce their individual distress, and there is some evidence that these approaches can increase the chance of the male drinker presenting for individual treatment (Halford, Price, Bouma, Kelly, & Young, 1998; Sisson & Azrin, 1986; Thomas & Ager, 1993).

Some programs for the wives of male problem drinkers were also aimed at helping the women to influence the men to reduce drinking. For example, Sisson and Azrin (1986) described helping women to identify high-risk settings for problem drinking, and suggested that wives schedule activities incompatible with drinking for high-risk times. Partners have also been encouraged to praise sobriety, and not to inadvertently reduce the negative consequences of drinking (e.g., by refusing to ring your partner's supervisor to say your partner is sick when he really has a hangover). Similar strategies were used by Halford et al. (1998). The only systematic evaluation of this approach was in the Halford study, which found that these strategies had little impact upon the drinker's alcohol consumption. The degree to which women actually implemented the suggested strategies was not evaluated, so it is unclear if women were unconvinced to implement the suggestions or if women changing these behaviors had little effect on the men's drinking.

In summary, CBCT is a well-established treatment for relationship problems which has demonstrated efficacy. CBCT is also very useful in the treatment of depression and alcohol problems of adults in committed relationships. However, common to all applications of CBCT and other approaches to couples therapy is a substantial input of time from therapists and couples. As described in the research and clinical literature, couples therapy typically involves anything from 12 to 30 sessions of conjoint therapy (e.g., Baucom & Epstein, 1990;

Greenberg & Johnson, 1988; Snyder et al., 1991a; Weiss & Halford, 1995). The time commitment and costs involved in all these approaches probably are a major disincentive to couples to seek assistance; only a small minority of distressed couples ever seek out therapy (Sanders, 1995; Wolcott & Glazer, 1989). Thus, even if CBCT were optimally effective for those who present for therapy, it would have modest impact on the community prevalence of relationship problems. This has led to attempts to prevent relationship problems.

6.28.6 PREVENTION OF RELATIONSHIP PROBLEMS

6.28.6.1 Prevention and Early Intervention

Programs to prevent relationship problems vary greatly along several dimensions, including the phase of the relationship at which they are targeted, the settings in which they are offered, the number and duration of sessions, the level of training of the service providers, the extent to which didactic vs. experiential forms of learning are emphasized, and the amount of group vs. dyadic interaction that occurs (Guerney, Guerney, & Cooney, 1985; Levant, 1986; Van Widenfelt, Markman, Guerney, Behrens, & Hosman, 1997). Existing programs can be usefully classified into two broad categories: (i) counseling and educational programs (e.g., Mace & Mace, 1976; Rutledge, 1968), and (ii) skill acquisition and cognitive restructuring programs (e.g., Guerney, 1977; Markman, 1984; Markman, Floyd, Stanley, & Lewis, 1986). Programs are based on a wide range of theoretical perspectives including social learning theory, Rogerian theory, and systems theory (Bradbury & Fincham, 1990). Regardless of theoretical orientation, all programs include efforts aimed at improving communication and problem-solving, negotiation of roles and responsibilities, clarification of values and expectations, sexuality and intimacy, developmental changes and transitions (e.g., parenting), and awareness of relationship dynamics.

The rationale for skills-based prevention of relationship problems is that acquisition of crucial relationship competencies are presumed to prevent problems. As noted earlier, research has identified these crucial competencies to include constructive communication and problem-solving skills, management of negative affect and conflict, realistic relationship beliefs and expectations, and promotion of positive behavior exchange (Markman, 1984; Notarius & Vanzetti, 1984). Programs designed to improve couples' abilities in these areas have been conducted both with couples planning marriage (e.g., Markman, 1981; Halford et al., 1994) and with married couples not experiencing relationship distress (e.g., Guerney, 1977; Miller et al., 1975).

Skills training prevention programs do increase couples' communication and problem-solving skills (Hahlweg & Markman, 1988; Markman et al., 1988; Miller, Nunnally, & Wackman, 1975). In their meta-analysis of controlled trials of such interventions, Hahlweg and Markman (1988) found an effect size of 1.51 on communication skills. Given that an effect size of 0.8 is generally considered a large effect size, this is a very impressive result. Couples in prevention trials are, by definition, currently satisfied with their relationships. Consequently, it is unlikely that prevention programs could produce large, immediate increases in relationship satisfaction above the pre-existing high levels. Consistent with this interpretation, Hahlweg and Markman (1988) report a mean effect size across seven premarital programs of 0.51 on relationship satisfaction, which is still a moderate size effect.

Over time many couples show declines in relationship satisfaction (Markman & Hahlweg, 1993), and the real test of prevention programs' effectiveness is whether the onset of relationship problems can be prevented. A significant methodological problem associated with evaluating prevention programs is devising appropriate comparison conditions for long-term controlled trials. If couples are randomly assigned to a no-intervention control when they desire intervention, they may seek intervention outside the study. On the other hand, failure to randomly assign to conditions can make interpretation of results difficult. Perhaps because of these difficulties few studies have assessed long-term outcome. A survey of 85 couple and family prevention and enrichment studies found that only 40% included follow-up measures at some point after post-test (mean follow-up was 12 weeks), with the longest follow-up assessment occurring at 12 months (Giblin, Sprenkle, & Sheehan, 1985). Only Markman and co-workers (e.g., Markman et al., 1988; Markman, Renick, Floyd, Stanley, & Clements, 1993) have reported follow-up data beyond two years.

Markman and co-workers found that skills-based marital distress prevention programs reduce marital violence (Markman et al., 1993), and the prevalence of marital separation and divorce over the first 5–10 years of marriage (Markman et al., 1993). However, these series of studies have a methodological problem. Subjects initially were recruited for a long-term follow-up study of marriage, and subsequently randomly assigned subjects to matched groups to be offered, or not offered, an intervention. Sixty percent of couples offered the relationship preparation program declined to participate. The two treatment conditions consist of those who accepted the program and their matched controls. As the treatment group were self-selected for agreeing to participate in the program, and the matched controls were not offered the program, there is confound between the conditions of self-selection.

Despite the limitations of the existing research, it is clear that skills-based prevention programs do modify aspects of couples' adaptive processes which are identified risk factors for relationship problems. The long-term maintenance of these behavioral changes needs further investigation, as do the long-term effects of these interventions on relationship problems, but preliminary results are encouraging.

6.28.6.2 Content of Prevention Programs

The content covered in skills-based prevention programs can be usefully considered as falling into six modules: (i) behavior exchange and positive intimacy enhancement, (ii) communication skills enhancement, (iii) management of conflict and negative affect, (iv) sexual enrichment, (v) gender role flexibility, and (vi) adaption to life transitions and maintenance of relationship satisfaction. We will consider each of these in turn.

Behavior exchange and positive intimacy enhancement procedures have been adapted from those used in couples therapy. As for therapy, the emphasis is on each partner self-selecting behavior change goals which enhance relationship functioning. In prevention programs this is often much easier to achieve than in therapy. In therapy, couple's negative feelings toward each other and possible ambivalence about the relationship often inhibit partners from making relationship enhancing efforts. Prevention program couples, by definition, have positive feelings about their partner and relationship.

Communication skills training involves individuals self-selecting goals for enhancing their own communication from an array of available skills and self-evaluating their own communication. This can be done by asking the couple to have a discussion. Immediately after the discussion both partners are asked to self-assess their communication using a checklist of potentially helpful communication behaviors set out on the form in Table 4. After completing the form, partners self-identify specific communication behaviors that each would like to increase in their repertoire in order to enhance their communication. This does not mean that the leader avoids responsibility for helping the partners to determine goals. Rather, the role of the leader is to help both partners to accurately self-evaluate their current communication and to develop specific, self-selected goals for enhancing communication.

Another exercise often used in communication skills training is to ask the couple to have a discussion at home which they audiotape. At the end of the discussion both partners self-evaluate their communication skills, formulate self-change goals, and then repeat the conversation building on the selected communication skills. Each partner then evaluates the impact of changing communication skills on the communication process. This procedure allows the partners to directly test the hypothesis that changing their communication behaviors in a particular way will enhance the relationship communication process. It also has the partners practice active self-correction of ineffective communication attempts.

Communication tasks that we recommend in relationship enhancement initially focus on nonconflictual topics. For example, we emphasize to couples the importance of discussing day-to-day occurrences on a regular basis, so as to keep informed and interested in the experiences of your partner. Consequently, we usually ask couples to have a series of discussions about what each does during the time they are apart. We also ask the couple to address ways in which they can support and show interest in each other's interests. This support might be in work, parenting, household chores, or in particular interests or hobbies. The relevant communication task is for one partner to initiate a conversation with their spouse about the spouse's interests and needs. Both partners are asked to identify ways in which they might be more supportive.

Conflict management is another important element of prevention programs. Once couples have a reasonable level of communication skills, they can then use these communication skills to handle difficult conflictual issues. In discussion of conflict management we describe the different settings in which conflictual topics may be discussed, and the fact that there are some settings in which it is easier to have a productive discussion than others. Couples are asked to consider the times, places, and circumstances in which they could most productively talk about topics which are difficult. Also couples are educated about the common maladaptive patterns in interaction around conflictual topics, such as the demand-withdraw and mutual avoidance patterns. Couples self-select goals which will help them to avoid those unhelpful patterns of interaction.

Table 4 Communication skills self-evaluation form.

Name: ______________________ Date: __________

The aim of this form is for you to identify your strengths and weaknesses in communication and to specify goals for improvement. Rate each of the skills below using this code:

0 — Very poor use of skill
1 — Unsatisfactory use of skill
2 — Satisfactory use of skill, but room for improvement
3 — Good use of skill
N/A — Not applicable

Skill	*0*	*1*	*2*	*3*	*N/A*
Specific descriptors					
Self-disclosure					
Clear expression of positives					
Assertive expression of negatives					
Attending to partner					
Minimal encouragers					
Reserving judgement					
Asking questions					
Summarizing content					
Paraphrasing feelings					

Self-identified strengths in communication: ______________________

____

Self-identified weaknesses in communication: ______________________

____

Another useful notion in relationship preparation programs is the idea of relationship rules for managing conflict. Relationship rules refer to the implicit assumptions and processes which couples develop for handling conflict. For exmple, some couples may believe that either partner should be able to raise any issue that is troubling them at any time. Other couples may feel that there is some responsibility to raise difficult issues at times and in places which maximize the chance of productive discussion. Table 5 lists some common relationship rules that couples may apply to managing conflict. Through discussion and negotiation couples can be asked to agree on relationship rules that increase their chance of managing conflict effectively.

Sexual enrichment is also an important element of many prevention programs. We make use of the widely available video tape *The lovers guide*. We would play this to couples, ask them to talk about their general reactions as a group, and then have the couples talk together in privacy about any goals they may wish to set in order to enhance their sexual experience. The video that we show is very sexually explicit, demonstrating ways in which one can enhance sensual and sexual pleasure, and identifies and describes some common sexual difficulties. We find that showing this tape is useful in helping couples to talk intimately about their desires to enhance their sexual relationship.

Gender role flexibility is another element of some prevention programs. Gender role flexibility refers to each partner taking some responsibility for a wide range of relationship maintaining activities, and transcending very rigid or traditional gender-based definitions of responsibilities. The notion of gender role flexibility can be introduced by asking both partners to identify which of a range of different behaviors, which potentially can be stereotyped as belonging to a woman or a man, they take responsibility for within the relationship. The potential value of being flexible in gender roles is in helping the couple adapt to changing life circumstances. For example, if both partners are able to earn an income, then the couple can adapt better if one person has difficulty obtaining work. Partners can be helped to self-identify specific behavior changes they wish to make in order to become more gender role flexible. For example, males may set themselves the target of learning to cook better, and women to learn how to maintain a car. An additional rationale for this process is that often the domestic responsibilities in families fall primarily on women, and this is a major source of relationship dissatisfaction for women. We point out to our male participants that women initiate approximately three-quarter of all divorce proceedings (Wolcott & Glezer, 1989). If men want to remain in happy relationships, then they need to ensure that they are domestically competent to contribute to the household.

In relationship preparation and enhancement programs it is important that couples prepare themselves for future changes in their relationship likely to result from major life transitions (Hahlweg & Markman, 1993). In one such exercise couples complete an adapted form of the life change event scale and are asked to rate the likelihood of these events occurring in the next one or two years and the probability that if those events occur they might have a negative effect on their relationship. For example, couples are asked to identify the ways in which events such as birth of a child, loss of a job, or a change of work circumstances might impact on their relationship. Partners are asked to self-select goals that they believe would help them adapt in a relationship-maintaining way to these life transitions. For example, a number of couples have identified that they may have reduced opportunities for having time together as a couple once they have children. They have

Table 5 Suggested ground rules for handling conflict.

1. We can bring up issues at any time, but the "listener" can say "this is not a good time" If listener does not want to talk at that time, he or she takes responsibility for setting up a time to talk in the near future (you need to decide on how "the near future" is defined)	_____ Yes	_____ No
2. When conflict is escalating we will call a "stop action" and (i) try it again, using the speaker/listener technique, (ii) agree to talk later at a specified time about the issue, using the speaker/listener technique	_____ Yes	_____ No
3. When we are having trouble communicating we will "engager" the speaker/listener technique	_____ Yes	_____ No
4. When using the speaker/listener technique, we will completely separate problem-*discussion* from problem-*solution*	_____ Yes	_____ No
5. We will have weekly "couple meetings" (you should set up a time now)	_____ Yes	_____ No
6. We will state when we have a problem, if we want to negotiate a relationship, or just solve the immediate problem	_____ Yes	_____ No

Source: Markman, Stanley, and Blumberg (1995).

then set individual goals, such as ensuring child minding is available or that they cultivate activities they can do at home, which increase the chance of having mutual shared enjoyable activities when they have young children.

In Table 6 we have set out the typical content of each of five 2 hour group sessions of a relationship preparation program. This is not a rigid schedule that must be followed, but rather a schematic representation about how a group might work. Sessions can be combined and homework resequenced to cover the same content in a full day, with one or two follow-up sessions.

6.28.7 CONCLUSIONS

Relationship difficulties are very common, and have a huge impact on adults and their offspring. The most common relationship problems are lack of relationship satisfaction, ambivalence about the future of the relationship, and problems in the adaptive interactional processes between partners. In the domain of the adaptive processes between the partners the most important factors contributing to relationship problems are poor communication, poor management of negative affect and conflict, unrealistic beliefs and expectations, and lack of positive shared experiences. Other important contributors to relationship problems are enduring vulnerabilities of the partners, such as individual psychological disorders and stressful life events. Couples lacking robust adaptive couple processes are likely to develop relationship problems when challenged by major life transitions and stressful events.

Cognitive-behavioral couples therapy is a well-established and effective means of helping many couples with relationship problems. Effective couples therapy uses the assessment process to help partners build a shared and constructive model of their relationship problems, and to define individual action that can improve the relationship. Therapy itself assists partners to self-direct a change process focused on enhancing positive exchange between partners, improving communication, and controlling destructive conflict. Adaptions of these procedures have been used successfully to teach currently satisfied couples to enhance their relationship and to prevent future relationship problems.

Preparation of this chapter was supported by an Australian Research Council Grant on

Table 6 Overview of typical content in a five session premarital skills training program.

Session	*Detail of content*
1	Introduction to group members; explain rationale for self-directed, skills training focused group program; identification of key behavioral domains promoting relationship intimacy; self-directed intimacy enhancement through self-directed goal setting and definition of homework task of behavior change; identification and modeling of key communication skills to enhance intimacy
2	Review of intimacy enhancement behavioral homework tasks; self-directed selection of further behavior change goals; review of key communication skills; guided self-evaluation of current communication skills; self-directed selection of communication enhancement goals and practice of implementation of those skills; self-directed goal setting and definition of homework task to enhance communication
3	Review of communication homework tasks, and self-directed further goals selection and definition of further homework task; introduction to the concept of the patterns of conflict and effective conflict management; negotiation with partner about relationship rules for managing conflict; self-directed goal setting for effective management of conflict; introduction to the concept of flexible gender roles, couple review of current gender roles, self-directed goal setting for future gender role flexibility
4	Review of communication homework task; review of the role of sexuality in relationship intimacy; couple discussion and goal setting to enhance sexual intimacy; introduction to the concept of partner support, self-directed goal setting to enhance partner support; self-directed definition of homework tasks to implement selected goals in areas of sexuality or partner support
5	Review of homework tasks; self-directed selection of any further goals to enhance relationship functioning; introduction of issue of maintenance of relationship functioning; self-directed identification of future life events impacting upon relationship; planning to promote relationship adaptation to predictable life events Closure

6.29.1 INTRODUCTION

Nowadays, more than half of all women diet because they believe they are too fat (e.g., Agras, 1990). In the late 1970s, one in every five of a sample of British women binged once a month, and 10% of these women regurgitated after bingeing in order to get the quantity of food eaten out of the system as quickly as possible (Wardle, 1980). Eating behaviors of this type can be problematic, but they are seen so frequently that they can no longer justifiably be categorized as "abnormal."

This chapter discusses eating disorders. Eating disorders differ from the problems mentioned above in the frequency and seriousness of the symptoms and the extent to which they interfere with the individual's functioning. With an eating disorder, the symptoms are much more serious and frequent than with an eating problem. Unlike an eating problem, an eating disorder is often dysfunctional: the patient suffers from it to an extent that it is virtually impossible to function normally. This is not always evident to others; the eating disorder bulimia nervosa, for example, can be concealed by sufferers for many years.

The eating disorders anorexia nervosa and bulimia nervosa, as well as atypical variations of these disorders and the recently identified binge eating disorder, are discussed in the present chapter. Because eating disorders are primarily seen among women, patients will be referred to as women. After a clinical description of the eating disorders, the diagnostic features, differential diagnoses, comorbidity and prevalence are discussed. Next, empirically validated theories of the origin and maintenance of eating disorders are considered. A final section discusses the effectiveness of the various treatments currently available.

6.29.2 ANOREXIA NERVOSA

The characteristic of a patient with anorexia nervosa is that she continually assumes that she is too fat. This conviction fuels an intense drive to be thinner, sometimes referred to as a relentless pursuit of thinness. The fervent desire to lose weight continually dominates the patient's thoughts, feelings, and behavior (Garfinkel, 1995). She eats only low-calorie food and exerts an enormous amount of physical effort, resulting in a loss of weight. Sleeping problems and depression can result from malnutrition. It is striking that neither the idea of being too fat nor the fear of gaining weight disappear as the weight loss continues. On the contrary, as weight decreases, the fear of becoming fat intensifies. Another striking aspect is that the patient usually denies the seriousness of the loss of weight.

Incessant attempts to lose an extreme amount of weight, and the belief among these underweight patients that they are still too fat, resulted in recent decades in the suspicion by numerous specialists and researchers that a distorted perception of the body is characteristic of patients with anorexia nervosa. Patients with anorexia nervosa were presumed to overestimate the size of their body. However, this clinical impression could not be irrefutably confirmed. Researchers asked patients, for example, if they could estimate the size of their body while viewing themselves on a video monitor. By turning knobs they could show on the screen how big they thought they were. It was learned that some patients with anorexia nervosa overestimate the size of their body more than others, while other patients with anorexia nervosa did not. Moreover, it was determined that people without an eating disorder also often overestimate their size (Garfinkel, 1995; Smeets, Smit, Panhuysen, & Ingleby, 1997).

The group of anorexia nervosa patients can be divided into two subgroups: the binge/purging type and the restricting type (American Psychiatric Association [APA] 1994). Purging refers to behavior oriented towards getting the food out of the body as quickly as possible: self-induced vomiting and the use of laxatives and diuretics (substances that stimulate the excretion of fluids: "pee pills"). Dieting, fasting, and sports activities are not considered purging behavior. An average of nine months after anorexia nervosa commences, about half of the patients start to suffer from uncontrollable bingeing and purging behavior (Polivy & Herman, 1985; Wardle & Beinart, 1981).

Purgers often stimulate the vomiting reflex by sticking a finger, toothbrush, or other oblong object into the desired position in the throat. After some time, some patients can stimulate this reflex simply by exerting a small amount of pressure on the stomach under the ribs. Vomiting is then more or less "automatic." Some chronic vomiters have a hard spot or callus on the back of the hand or under the ribs. This callus results from the hand rubbing along the teeth or from exerting pressure on the stomach.

The use of laxatives is not as effective as the patient often believes. Laxatives rinse food through the intestines at an accelerated speed. This rapid journey through the digestive track can prevent complete absorption of the nutrients, as a result of which somewhat less energy (kilocalories) is absorbed. The weight loss achieved in this manner, however, is small and short-lived because the laxatives primarily stimulate the excretion of fluids. The weight lost is regained after drinking a few glasses of fluids. A paradoxical effect of the long-term use of laxatives is that constipation occurs because of the reduced or complete loss of activity of the intestines.

Patients of the other, restricting type do not suffer from binges. These patients continually restrict their intake of food and therefore do not turn as easily to the purging measures explained above. Which factors determine when and why a patient changes from a restricting type to a purging type with binges is unknown. The two groups do, however, differ in a number of other ways: on average, the bingeing/purging type has a higher weight before the anorexia nervosa started and suffers more often from disorders involving controlling impulses, excessive use of alcohol or drugs, mood disorders, and personality disorders (Garfinkel, 1995).

Malnutrition and purging behavior have medical consequences. The menstrual cycle is usually interrupted, and when underweight becomes extreme the menses cease. The extremities (fingers, toes) are cold and turn purple-blue (this is referred to as cyanosis), the body temperature is low (hypothermia), which can result in a downy layer of hair growing on the body (lanugo), the blood pressure is low (hypotension), and the heartbeat is slow (often lower than 60 beats per minute: in medical terms bradycardia). The metabolism is also often slow. The physical consequences of malnutrition often disappear once the eating pattern and weight have returned, but this can take some time.

The diagnostic criteria for anorexia nervosa according to the *Diagnostic and statistical manual of mental disorders* (4th edn., *DSM-IV*) are listed in Table 1.

6.29.3 BULIMIA NERVOSA

A chaotic eating pattern, weight-control measures, and irrational ideas about one's figure, appearance, and weight are characteristic of the eating disorder bulimia nervosa (APA, 1994). Normally, periods of sparse eating alternate with binge eating episodes (bulimia literally means "as hungry as an ox"). During a binge, in an uninterrupted period of time an amount of food is consumed that is considerably larger than most people would normally eat in the same period of time. Typical is the subjective feeling of loss of control over eating: during the binge, the patient feels as if she can no longer stop or control what or how much she eats (Fairburn & Wilson, 1993). The binge can be induced by a variety of stimuli: fluctuating moods (e.g., depression, fear, euphoria), the breaking of idiosyncratic diet rules, for example, by eating "forbidden" food (i.e., food rich in calories), and a craving for food stimulated by the smell of palatable food (Jansen & van den Hout, 1991). Some patients describe a type of dissociative amnesia: they experience their binge as a dream and cannot remember the details. After bingeing, in the very short term, the binge improves affect, but very soon thereafter (often even before the end of the binge) the subject feels guilty and self-disgusted. The patient is afraid of gaining weight and seeks refuge in the compensational behavior described above: purging and dieting.

The chaotic eating pattern (alternating between much and little) results from extreme worry about the figure, appearance, and weight. Like patients with anorexia nervosa, despite the fact that their weight is often normal, patients with bulimia nervosa believe they are heavy, slow, and fat (Phelan, 1987). These irrational ideas about their figure and weight determine to a significant degree their self-esteem, which is often low.

Patients with bulimia nervosa also have irrational cognitions about things other than their body shape and weight. Their ideas about food and eating are also dysfunctional (Dritschel, Williams, & Cooper, 1991). Everything that is edible is either "good" or "bad." Good food is food that has a low amount of kilocalories (e.g., skimmed yogurt, bouillon, and lettuce); bad food is food with a high amount of calories, and is "forbidden" (e.g., chocolate, pizza, and fried meat). Eating a bit of forbidden food is "completely" bad. This dichotomous (black-and-white) thinking style is an invitation to failure: the stricter the rules they apply to themselves, the more likely the rules are to be broken.

Bulimia nervosa, like anorexia nervosa, is often accompanied by medical complaints that result from the binges, vomiting, fasting, and use of laxatives and diuretics. Most of these complaints are reversible and disappear as soon as the eating behavior has normalized. Some, however, are life threatening. When vomiting

Table 1 *DSM-IV* diagnostic criteria for 307.1 anorexia nervosa.

A. Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected)
B. Intense fear of gaining weight or becoming fat, even though underweight
C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight
D. In postmenarcheal females, amenorrhea, i.e., the absence of at least three consecutive menstrual cycles (a woman is considered to have amenorrhea if her periods occur only following hormone, e.g., estrogen, administration)

Specify type:

Restricting type: during the current episode of anorexia nervosa, the person has not regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas)

Binge-eating/purging type: during the current episode of anorexia nervosa, the person has regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas) and using laxatives and diuretics, the patient loses a significant amount of fluids. This dehydration may result in thirst, dry skin, dizziness when rising from a sitting or horizontal position, light-headedness, and fainting. Chronic purging can also result in serious disorders of the electrolyte balance. Electrolytes (the most important of which are sodium, potassium, and chloride) are called just that because they are responsible for the transmission of electrical signals between the cells in our body. They play an important role in metabolic processes and ensure that the nerve and muscle cells function properly. As a result of purging, a considerable quantity of electrolytes, in particular sodium and potassium, are excreted. Serious shortages can be life threatening because the heart muscle is weakened and receives insufficient impulses to compress and then relax. A simple blood test can indicate whether the electrolyte levels are abnormal.

The *DSM-IV* criteria for bulimia nervosa are listed in Table 2.

6.29.4 OBESITY AND BINGE EATING DISORDER

Obesity refers to an excess of body fat. Because body weight and body fat are highly correlated, overweight is often used as a proxy for obesity (Brownell, 1995; Wardle, 1995). To determine whether someone's weight is in or outside the normal range, the body mass index (BMI) is generally used. The BMI refers to the ratio of height and weight; it is calculated by dividing body weight (in kilograms) by height^2 (in meters). For example, the BMI of a subject weighing 63 kg and 1.68 m tall is: $63/(1.68)^2 = 22.3$. A BMI between 20 and 25 shows a healthy weight. The more a BMI drops below 20, the more severe the underweight is, and, vice versa, the more the BMI rises above 25, the more severe the overweight (see Table 3). Levels of BMI greater than 30 are usually taken to indicate obesity.

In most cases, obesity develops in the absence of any medical disease (Foster, 1992), but it is a risk factor for a range of major health hazards, including cardiovascular diseases, hypertension, diabetes, stroke, hypercholesterolemia, gallbladder diseases, and osteoarthritis (Wardle, 1995; Willett & Manson, 1995). Statistics from life insurance companies show a significant increase of morbidity and mortality when the BMI rises above 30. The health consequences are more serious for the obese with fat around the waist (the "apple") than for obese subjects with fat around the hips and thighs (the "pear").

Stigmatization, prejudice, and discrimination of the obese, for example, in relation to acceptance for a job, makes obesity a psychological problem as well. Obesity is considered unattractive in Western cultures, leading to negative self-images and even self-hate in obese persons, especially women (Foster, 1992; Stunkard & Wadden, 1992). Children as young as six years of age describe silhouettes of obese children as "lazy, dirty, stupid, ugly, cheats, and lies," and they rate children with a variety of disabilities as more attractive than the obese children (Rodin, Silberstein, & Striegel-Moore, 1984). Low self-esteem, feelings of anxiety, depression, and guilt are frequently seen in the seriously obese (Stunkard & Wadden, 1992).

Following the definitions of *DSM-IV*, obesity is not defined as an eating disorder or even as a

Table 2 *DSM* diagnostic criteria for 307.51 bulimia nervosa.

A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
  (1) eating, in a discrete period of time (e.g., within any 2 hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances
  (2) a sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating)
B. Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting, misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise
C. The binge eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months
D. Self-evaluation is unduly influenced by body shape and weight
E. The disturbance does not occur exclusively during episodes of anorexia nervosa

Specify type:

Purging type: during the current episode of bulimia nervosa, the person has regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas

Nonpurging type: during the current episode of bulimia nervosa, the person has used other inappropriate compensatory behaviors, such as fasting or excessive exercise, but has not regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas

Table 3 Body Mass Index.

BMI	*Weight category*
<18	Severe underweight
18–20	Underweight
20–25	Normal weight
25–27	Slightly overweight
27–30	Overweight
>30	Obesity
30–35	Mild obesity
35–40	Moderate obesity
>40	Morbid or severe obesity

Body Mass Index (BMI) = weight/height^2; kg/m^2.

mental disorder. Until recently, obesity has generally been studied by doctors and biologists, whereas eating disorders have always been within the scope of psychologists and psychiatrists. However, in the last few years, interest in obesity among psychologists and psychiatrists has been growing. One of the main reasons for this renewed interest is the recognition of increased psychopathology in some obese people.

This subgroup of the obese population frequently overeat in a way which could be described as bingeing. Some of these obese binge eaters meet the diagnostic criteria of bulimia nervosa, but most of them do not. Those who do not meet the criteria binge regularly but do not engage in the characteristic compensatory purging behaviors of bulimia nervosa, that is, self-induced vomiting or use of laxatives. *DSM-IV* considered this a possible eating disorder and called it the Binge Eating Disorder. In the diagnostic handbook, binge eating disorder is included in an appendix listing clinical presentations which must be studied in detail before they can be definitely included in a diagnostic category in the handbook. In Table 4 the preliminary *DSM-IV* criteria for binge eating disorder are listed.

Obese subjects who meet the criteria for the binge eating disorder differ on several characteristics from obese persons who do not meet the binge eating disorder criteria (Brody, Walsh, & Devlin, 1994; Castonguay, Eldredge, & Agras, 1995; Fichter, Quadflieg, & Brandl, 1993; Lowe & Caputo, 1991; Spitzer et al., 1993). Obese binge eaters in general have a higher body mass index, report more weight fluctuations, show an earlier onset of obesity, spend more time dieting, are more restrained in their eating patterns, drop out of treatment more frequently, have poorer treatment outcomes, and show more psychopathology than the obese nonbingers.

Observed links between obesity and psychopathology (see Section 6.29.6.2) are mostly accounted for by binge eating; it is the severity of binge eating and not the severity of obesity which is correlated with the indices of psychopathology (Castonguay et al., 1995). Note, however, that the obese nonpurging binge eaters show less psychopathology than the purging bingers, i.e. subjects with bulimia nervosa.

6.29.5 ATYPICAL EATING DISORDERS

About one-third of the patients who presented in England for the treatment of an eating disorder failed to meet the diagnostic criteria for anorexia or bulimia nervosa (Fairburn & Walsh, 1995). They normally have an atypical eating disorder or, in *DSM-IV* terms, an eating disorder "not otherwise specified" (APA, 1994). These are people who, for example, meet all of the criteria for anorexia nervosa except that they still have a regular menstrual cycle, or they have lost a considerable amount of weight, but the weight is not low enough. A patient may also meet all of the criteria for bulimia nervosa except that the binges do not occur frequently enough.

6.29.6 DIFFERENTIAL DIAGNOSES AND COMORBIDITY

6.29.6.1 Differential Diagnoses

Considerable weight loss can occur as a result of certain physical illnesses (e.g., cancer, intestinal disorders, and AIDS), depression, schizophrenia, and others. Weight loss of this type must be distinguished from anorexia nervosa if the patient fails to meet the other diagnostic criteria for the eating disorder, such as an extreme fear of being fat and the desire to continue to lose weight.

Binges can occur as a result of schizophrenia, depression, a borderline personality disorder, and certain neurological disorders such as the Kleine–Levy syndrome. If these patients do not show compensation behavior and do not appear extremely overly concerned with their figure, they do not meet the criteria for bulimia nervosa.

If patients with an eating disorder handle food compulsively or are afraid of eating in social situations, they do not necessarily suffer from an obsessive-compulsive disorder or from social anxiety. It must first be determined whether the patient also meets the other criteria for these disorders and whether, for example, they also suffer from obsessions, compulsions, or social fears that are not related to food or the figure.

Table 4 *DSM-IV* research criteria for Binge Eating Disorder.

A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
  (1) eating, in a discrete period of time (e.g., within any 2 hour period), an amount of food that is definitely larger than most people would eat in a similar period of time under similar circumstances
  (2) a sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating)
B. The binge eating episodes are associated with three (or more) of the following:
  (1) eating much more rapidly than normal
  (2) eating until feeling uncomfortably full
  (3) eating large amounts of food when not feeling physically hungry
  (4) eating alone because of being embarrassed by how much one is eating
  (5) feeling disgusted with oneself, depressed, or very guilty after overeating
C. Marked distress regarding binge eating is present
D. The binge eating occurs, on average, at least 2 days a week for 6 months
  Note: The method of determining frequency differs from that used for bulimia nervosa; future research should address whether the preferred method of setting a frequency threshold is counting the number of days on which binges occur or counting the number of episodes of binge eating
E. The binge eating is not associated with the regular use of inappropriate compensatory behaviors (e.g., purging, fasting, excessive exercise) and does not occur exclusively during the course of anorexia nervosa or bulimia nervosa

6.29.6.2 Comorbidity

Obese bingers more often than obese nonbingers are characterized by depression, anxiety, personality disorders, low self-esteem, impulsivity, body perception disturbances, neuroticism, and overall distress. Obese binge eaters significantly more often meet criteria for a psychiatric disorder than obese nonbinge eaters (60% vs. 28%; Castonguay et al., 1995). Some authors consider depression a risk factor for the occurrence of binges among people who are overweight (Marcus, 1995).

Nearly half of women suffering from anorexia nervosa and bulimia nervosa are depressive, whereas others show obsessions and compulsions or other anxiety disorders. Their first-degree relatives suffer from mood disorders more often than could be expected by chance (Cooper, 1995a). In particular, patients who regularly purge are clearly more depressed and show more anxiety than those who do not regularly purge (Garner, 1993). This is why from time immemorial there have been experts who believe that eating disorders are a variation of mood and/or anxiety disorders (Garfinkel, 1995), but the symptoms of anxiety disorders and depression occurring during the eating disorder are virtually always secondary to the eating disorder. When the eating disorder disappears, the depressive and/or phobic characteristics often disappear as well (Fairburn & Cooper, 1989).

Recently, Welch and Fairburn (1996b) found that deliberate self-harm by repeated cutting was much more common among a community sample of bulimia nervosa subjects (19%) than among a psychiatric (3%) and a normal (1%) control group. Although it is a general clinical impression that subjects with eating disorders show a high incidence of psychoactive substance abuse, controlled epidemiological studies do not confirm this (Welch & Fairburn, 1996b; Wilson, 1991). Also, a borderline personality disorder is considered to be much more prevalent among subjects with eating disorders, in particular bulimia nervosa, than among other psychiatric populations. Rates have ranged from 2% to 47% (Wonderlich, 1995). However, methodologically sound studies are rare; the main problems in these studies are the absence of (psychiatric) control groups and the diagnostic problems related to the definition of the borderline personality disorder. There is considerable overlap between the diagnostic criteria for eating disorders and the diagnostic criteria for the borderline personality disorder. The latter includes, for example, binge eating, mood fluctuations, unstable self-image, suicidal or self-mutilating behavior, feelings of boredom and emptiness. Because of the overlap in criteria, there is a risk of overdiagnosing the borderline personality disorder among (depressed) subjects with eating disorders. This idea is supported by data that indicate a decrease in the rate of borderline personality disorders with short-term, symptom-focused interventions (Wonderlich, 1995).

6.29.7 PREVALENCE AND PROGRESS

Anorexia and bulimia nervosa are seen significantly more often among women than men. About 10% of the patients are male (APA, 1994). Epidemiological research into the prevalence of the two eating disorders suggests that about 0.5–1% of girls and young adult women

(18–30 years) suffer from anorexia nervosa, while bulimia nervosa is seen in 1–3% of this group (APA, 1994; Fairburn & Beglin, 1990). Atypical eating disorders are considered to be much more common (APA, 1994; Fairburn & Walsh, 1995), but how common is currently unknown. It is difficult to collect exact data concerning the prevalence of eating disorders. In addition to the fact that women with anorexia nervosa often deny that they have an eating disorder and women with bulimia nervosa often keep their problem hidden because they are ashamed, research of this type requires precise, unambiguous application of the diagnostic criteria.

Some researchers believe that the prevalence of the two eating disorders has increased in recent decades (APA, 1994). Epidemiological studies, however, do not show an upward trend in rates (Fombonne, 1996). The alleged increase could be a result of the increased publicity about and familiarity with eating disorders, as a result of which cases are identified more quickly. Patients or relatives turn to their family physician or another expert more readily, and the diagnostic process and the available assistance have improved, so that an eating disorder is more readily recognized by all concerned.

Obesity is much more common than the eating disorders anorexia and bulimia nervosa. In the USA 12% of adult men and 15% of adult women are obese, in the UK 8% and 12%, respectively (Wardle, 1995). Binge eating disorder is primarily seen in overweight people and one and a half times more often in females than in males (APA, 1994; Marcus, 1995). About 2–5% of overweight nonpatient community subjects meet criteria for the binge eating disorder, compared with one-third of overweight people who present for treatment. The higher the BMI, the greater the likelihood of binge eating.

Obesity is more prevalent in lower than in higher socioeconomic groups (Foster, 1992), whereas anorexia and bulimia nervosa occur to about the same extent in all social classes (Fairburn & Beglin, 1990; Gard & Freeman, 1996; Rogers, Resnick, Mitchell, & Blum, 1997) and appear to be more common in industrialized countries, where there is an excess of food and the "perfect figure" culture prevails, than in undeveloped countries. However, we do not know this for certain, because systematic studies of the prevalence in other cultures are seldom made. Women in certain professions run a higher risk than other women: anorexia nervosa is seen relatively more frequently among ballet dancers, models, and athletes (professions in which a low body weight is an advantage), but it is not clear whether these professions stimulate the eating disorder or people with (a predisposition for) an eating disorder choose these professions.

Anorexia and bulimia nervosa usually start prior to the age of 18. In 10% of the cases in which hospitalization is required, anorexia nervosa results in death (APA, 1994). The progress of the two eating disorders is highly variable. Some people are cured after a short episode of anorexia nervosa, while some regularly relapse and others suffer chronically from the disorder. The younger anorexia nervosa starts and the shorter the time between onset and presentation for treatment, the better the prognosis. The progress of bulimia nervosa varies: 20% of the treated cases suffer chronically from the eating disorder and 30% relapse now and then, in which cases periods of bulimia nervosa alternate with periods of normal eating behavior (Hsu, 1995). Fifty per cent of bulimics remain completely free of symptoms up to 10 years after cognitive-behavior therapy (Hsu, 1995). Figures for untreated cases are not available.

6.29.8 ETIOLOGY

A number of influential theories concerning the origin and maintenance of eating disorders are discussed in this section. Their empirical validity is also examined.

6.29.8.1 Genetics

The fact that first-degree relatives of anorexia and bulimia nervosa patients suffer from an eating disorder more often than could be expected by chance is often presented as proof that eating disorders are genetically determined. This conclusion is not justified: a higher prevalence of eating disorders among relatives does not establish the genetic nature of the disorders. Such evidence can only be supplied by disentangling the influence of inherited factors from environmentally transmitted factors, for example, through studies of twins or adopted children. By studying concordance rates of eating disorders among monozygotic (MZ) and dizygotic (DZ) twins, Treasure and Holland (1995) found significantly more MZ pairs concordant for anorexia nervosa than DZ pairs. This was not the case for bulimia nervosa, suggesting that genetic factors play a significant role in the development of anorexia nervosa, whereas this may not be true for bulimia nervosa. Thus, both eating disorders tend to run in families, but, for the origin of bulimia nervosa, environmental factors also appear to be important. Genetic influences may be more important in the development of anorexia nervosa. The nature of inherited factors in anorexia and bulimia nervosa needs to be examined more closely.

The cause of obesity is still poorly understood. It is clear that obesity is always caused by a greater energy intake over output, but the cause of the energy imbalance is unknown. Obesity runs in families. Whether this results from genetic factors or family eating patterns or maybe both is yet unknown. Adoption studies point to a heredity factor for body weight: they show that adopted children have weights more closely related to their biological than to their adoptive parents, and monozygotic twins resemble each other more than dizygotic twins, whether they have grown with each other or not (Foster, 1992). According to some experts, the heritability factor is not a gene for excess body weight, but a vulnerability to obesity that is expressed under suitable environmental circumstances (Drewnowski, 1996; Wilson, 1994). There are also some indications that the obese are characterized by inherited metabolic efficiency which enables them to gain or maintain weight easily. For example, obese children tend to have obese parents, and research has shown that the energy expenditure of normal weight offspring of obese parents was only about 80% of that found in normal-weight children of nonobese parents (Foster, 1992). However, there is also evidence for distorted eating patterns in the obese. In general, obese persons are found to eat more than their lean counterparts, and there are indications that childhood obesity is triggered by overeating (Foster, 1992). Moreover, the obese show a preference for fat, and their diet indeed is richer in fat than diets of lean persons. Children's preferences for fat food were not only influenced by their own body fatness, but also by the fatness of their mother, which led Drewnowski (1996) to hypothesize that the genetic vulnerability is an increased appetite for energy-dense fat-containing foods.

6.29.8.2 Childhood Sexual Abuse

The fact that a large proportion of patients with eating disorders and people who have suffered from sexual abuse have low self-esteem and tend to feel shame about their body led some authors to relate childhood sexual abuse to the development of eating disorders (e.g., Andrews, 1997). Some recent large-scale and well-controlled studies show that self-reported childhood sexual abuse is present in about 25–35% of the eating-disordered subjects (Vize & Cooper, 1995; Welch & Fairburn, 1994; 1996a). Welch and Fairburn (1994) found a rate of 26% for sexual abuse in a community sample of subjects with bulimia nervosa. This was significantly more than the rate of sexual abuse in a normal control group (10%) but no different from the rate of sexual abuse in community controls with other psychiatric disorders (24%), like affective disorders or anxiety disorders. Thus, childhood sexual abuse is not directly relevant to most cases of eating disorders, and the data suggest that childhood sexual abuse is a nonspecific risk factor for the development of psychopathology in general and not for the development of eating disorders in particular. However, self-report data have serious limitations: over-reporting, under-reporting, and retrospective distortion may play parts in skewing the data, suggesting that care is needed in their interpretation (Esman, 1994), especially when the influence of neuroticism and depression is not controlled for.

6.29.8.3 Dieting for the Perfect Figure

It has been found in many studies that physically attractive people are considered to be overendowed with favorable qualities. Beautiful people are considered more interesting, stronger, friendlier, more intelligent, and more sexually exciting than less beautiful people; appearance is unrelated to these qualities. As a result of the wonderful qualities attributed to attractive people, their lives become even better than they would otherwise be: they are more likely to receive assistance during conflicts, are more likely to get the job they apply for, and are less likely to be found guilty in a court of law (Feingold, 1992).

It has therefore been suggested that the media systematically present distorted information about the ideal figure and the perfect body, dictating weight standards that are unobtainable for women or only obtainable by considerable effort; being beautiful makes life much more pleasant while being fat is generally not considered attractive; therefore many women use extreme measures to lose weight and consequently develop an eating disorder.

A number of facts appear to support this train of thought. Eating disorders are seen much more often among women and girls than among men and boys. Eating disorders are also reported to be more common in the Western, industrialized countries where women compare themselves to extremely skinny models than in non-Western cultures where this type of figure is not considered to be as ideal. Women with a typically female distribution of fat (broad hips, buttocks, and upper legs) suffer more often from eating disorders than women with a figure that is more male (narrow hips, buttocks, and legs). Lesbians suffer less often from eating disorders than heterosexual women, while homosexual men are more likely to develop eating disorders than heterosexual men (it is assumed that homosexual women are less influenced by the ideal female figure, while outward appearance is more important to homosexual men than to heterosexual men) (Brand, Rothblum, & Solomon, 1992). In our culture, a slim figure is appreciated and striving to lose weight causes a lot of women eating problems, simply because they inherited a figure which—according to our cultural standards—is not ideal.

The idea that our culture overvalues the "perfect figure" and therefore causes eating disorders is, nevertheless, an oversimplification of the facts. The perfect-figure culture is something that is applicable to all women in Western society. If the perfect-figure culture did in fact cause eating disorders, there would be epidemics of these disorders. This is not the case. It would appear more likely that the "perfect-figure culture" stimulates women to diet to lose weight, thereby increasing the risk of an eating disorder. Why?

Binges go hand in hand with the intention to limit the intake of food (Polivy & Herman, 1985); retrospectively, it was found that about 80% of patients with bulimia nervosa tried to lose weight by strict dieting prior to the onset of binge eating (Rossiter, Wilson, & Goldstein, 1989); about 50% of anorexia nervosa patients develop binge eating episodes about 9–18 months after the onset of strict dieting (Polivy & Herman, 1985); and nonclinical dieters report significantly more binge eating than nondieters (Wardle, 1980).

The set-point theory explains the relationship between dieting and binge eating. According to that theory, every organism has a certain amount of fat that has been predetermined for life. The idea is that the amount of fat present in an organism is continuously registered. A homeostatic mechanism is responsible for keeping the amount of fat balanced. If, in comparison with the predetermined amount of fat, a shortage of fat is identified, processes are activated that bring the quantity of fat up to the set-point level. If too much fat is identified, processes are activated that bring the quantity of fat back down to the set-point level (Keesey, 1995). According to this theory, people with a low set-point weight in our "perfect-figure" culture are just plain lucky. The people with bad luck—a high set-point weight—are condemned to being "overweight" for their entire lives. When these people—for instance, when influenced by the concept of a "perfect-figure'—start to diet and lose weight, their weight drops below their own set-point weight. Then the body responds with mechanisms designed to regain weight: bingeing and a slower metabolism can be triggered. According to the set-point theory, patients with bingeing urges have dropped below their set-point weight.

The theory is elegant, but there are a few anomalies. In the first place, patients with anorexia nervosa are the perfect example of malnourished dieters. Nevertheless, only half of these patients report suffering from bingeing urges. Second, there are dieters who never overeat; they are called "successful" dieters. A German study indicated that about one-half of every one thousand women diet without any problems (Westenhoefer, Pudel & Maus, 1990); in England and the USA, documented studies indicate that "only" 8–9% of dieting women and girls suffer from bingeing urges or develop an eating disorder (Agras, 1990; Patton, Johnson-Sabine, Wood, Mahn, & Wakeling, 1990). The set-point mechanism is therefore not nearly as dominant as suggested. Apparently, many people can diet and lose weight to below the set-point level without any problems. Furthermore, it does not appear likely that dieters with bingeing urges are below their set-point weight: a number of studies have indicated that dieters have a higher BMI and eat the same amount or even more kilocalories (and retain that energy) than nondieters (see, e.g., Jansen, 1996). Of course, one might put forward the untestable and circular argument that the bingeing dieters have a higher set-point than the normal eaters; advocates of the set-point theory still have the formidable task of discovering how a person's set-point weight can be determined.

Studies of the relationship between dieting and bingeing are usually retrospective or correlative and they thus do not render any certainties with reference to causality. It therefore cannot be proven that dieting is not a consequence of a tendency to regularly overeat or that there is not a third factor involved; an underlying mechanism that explains both the dieting and the bingeing.

Briefly summarized: the "perfect-figure" culture prescribes a female figure that most women will never be able to achieve. This is why many women diet. In about 9% of the cases, dieting results in an eating disorder. This makes it improbable that the "perfect-figure" culture and dieting are the key determinants of eating disorders; if this were the case, a considerably larger number of women would suffer from eating disorders.

6.29.8.4 Serotonin Depletion

First-degree relatives of patients with an eating disorder not only have eating disorders more often, but mood disorders are also more common than would be expected. Nearly half of patients with eating disorders are also diagnosed as suffering from depression (Laessle, 1990). The association of the two disorders within families and individuals led to the hypothesis that eating disorders are in fact a type of biological mood disorder. This will be discussed further below.

Various studies identified a relationship between eating carbohydrates and mood. Eating a proportionately large amount of carbohydrates results in a better mood (Fichter & Pirke, 1995; Jansen, van den Hout, & Griez, 1989; Wurtman & Wurtman, 1984). This mood improvement is assumed to be mediated by the neurotransmitter serotonin: by eating relatively large amounts of carbohydrates and little protein, serotonin production in the brain increases. The increased serotonergic activity results in mood improvement. A shortage of carbohydrates, by contrast, results in a decrease in the amount of serotonin in the brain. In turn, this results in a lowering of mood.

The amount of serotonin in the brain determines not only mood state but also the craving for carbohydrates. As the amount of active serotonin decreases, an increased craving for carbohydrates is observed. It can therefore be hypothesized that the production of serotonin in the brain is in part dependent on the amount of carbohydrates consumed. Eating a larger amount of carbohydrates results in more serotonin being produced in the brain. As a result, mood improves and the craving for carbohydrates diminishes. If, however, too few carbohydrates are consumed, less serotonin is produced, mood declines, and the craving for carbohydrates increases.

Animal experiments have shown that deprivation of carbohydrates seriously disrupts the carbohydrate regulation as described above. After rats were deprived of carbohydrates for a short period, cerebral sertonin level decreased as predicted. It was striking that serotonin did not reach the normal level again until after an excessive amount of carbohydrates was consumed (Wurtman & Wurtman, 1984).

These and other findings resulted in the following hypothesis concerning the origin of binges among patients with bulimia nervosa (see also Figure 1): for a variety of reasons, for example the desire to fulfill the cultural ideal of the female figure, some women subject themselves to a rigid eating regime. If this eating regime results in too few carbohydrates being consumed, successfully following the strict regime will result in disruption of the serotonergic system on the cerebral level. By depriving themselves of carbohydrates for longer periods of time, consumption of carbohydrates later will not immediately result in the required increase in serotonin. This increase will not be achieved unless excessive amounts of carbohydrates are consumed during a binge. A binge could, therefore, be considered a type of "self-medication."

Indeed it was found, analogous to the finding from the animal experiment of the Wurtmans (Wurtman & Wurtman, 1984), that the consumption of a standard quantity of carbohydrates by patients with bulimia nervosa did not result in the expected increase in the tryptophan ratio. Tryptophan is a large neutral amino acid, and its ratio to other large amino acids determines the amount of tryptophan entering the brain. A larger ratio means more tryptophan entering the brain, resulting in increased serotonin levels in the brain. What's more, eating carbohydrates did not stop until the tryptophan ratio in the blood plasma reached a normal level (see Pirke, 1995). Others found a lower concentration of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) in the cerebrospinal fluid (CSF) of severe bulimic patients (Jimerson, Lesem, Kaye, & Brewerton, 1992). The quantity of 5-HIAA in the CSF reflects the amount of serotonin active in the brain; the data thus point to a low turnover of 5-hydroxytryptophan (5-HT) in subjects with severe bulimic symptoms. However, a study with weight-restored anorexics indicates that abnormalities in central serotonin function *follow* from weight loss and malnutrition and are not related primarily to the disorder itself (Odwyer, Lucey, & Russell, 1996).

Caution is also advised when the findings are presented as evidence supporting the theory that binges serve to increase the quantity of serotonin in the brain. In the above-mentioned studies, it is assumed that the food patients consume during binges is rich in carbohydrates, whereas this is not the case. It has repeatedly been found that patients with bulimia nervosa eat as much carbohydrates during the binges as they do in between binges (Jansen, van den Hout, & Griez, 1989; Walsh, 1993). Moreover, in both periods they consume the same amount of carbohydrates as a normal control group. However, it should also be noted that a recent study among healthy female subjects shows that even moderate dieting on a diet with a normal macronutrient composition (1000 kcal, 31% protein, 44% carbohydrate, 25% fat) causes increased sensitivity of 5-HT receptors in the brain (Cowen, Clifford, Walsh, Williams, & Fairburn, 1996), suggesting that the overall decrease in the neurotransmission of serotonin during dieting does not require a relative carbohydrate depletion.

The serotonin hypothesis concerning the origin of bingeing is important, but it must as

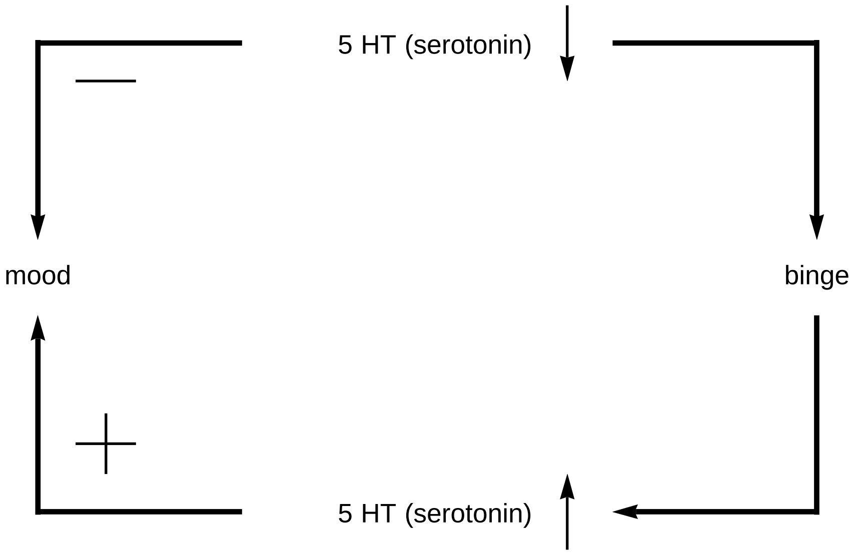

Figure 1 The serotonin model of binge eating.

yet be proven that the bingeing truly serves to increase the serotonin level in the brain. Findings suggesting that other psychiatric disorders may be characterized by low serotonin levels in the brain also generate the question of why these patients do not suffer from bingeing as a type of self-medication.

6.29.8.5 The Learned Nature of Binge Eating

Recent studies in the area of addiction suggest that the urge to consume a substance is a classically conditioned response (Drummond, Tiffany, Glautier, & Remington, 1995; Siegel, 1983). Addicts normally use a substance in the presence of certain stimuli, for example, their favorite pub, drinking or shooting buddies, the bottle, the syringe, the spoon and the silver foil. In a long series of experiments, it was shown that stimuli the nature of their exclusive presence eventually predict the use of a substance resulting in the addict having preparatory physiological reactions. Even before any substance is swallowed, injected, or inhaled, changes occur in the body. These anticipative physical changes are said to be experienced as a virtually uncontrollable urge to consume the substance, and striking is the fact that the occurrence of physical reactions after successful withdrawal accurately predicts a relapse (Drummond et al., 1995).

Patients with bulimia nervosa show some striking similarities with addicts. Both are preoccupied with the substance that they use excessively, both experience an urge to consume the substance, and both are characterized by loss of control during consumption. The analogy between bulimia nervosa and addiction may teach us something about the origin of binges. Excessive consumption of food during a binge is often related to a configuration of specific stimuli. Think in this respect of seeing, smelling, and tasting rich food, emotional confusion (a somber mood, fear, boredom, or loneliness), certain disinhibiting thoughts, and the time of the day. When repeatedly and exclusively combined with the bingeing, these stimuli become excellent predictors for a binge. Impressive data from experiments with animals indicate that eating behavior can be induced by stimuli that are repeatedly associated with the intake of food (Wardle, 1990; Woods, 1991).

According to this theory, the stimuli that predict the binge continually induce preparatory physiological responses in the eater (see Jansen, 1994, in press). The model predicts that the physiological responses are experienced as a virtually irresistible urge to consume food and therefore increase the chance of a binge. It remains, however, to be seen whether this model for the origin of binges will be confirmed by empirical studies.

6.29.8.6 Dysfunctional Cognitions

Excessive worry about the figure, appearance, and weight, as already indicated, is characteristic for patients with an eating disorder. The extreme worries about appearance and weight probably represent the core of the eating disorders. Thinness is idealized, and the feeling of being fat fuels the drive to lose weight. Eating-disordered subjects continually evaluate themselves in terms of outward appearance and weight. They tend to judge self-worth almost exclusively in terms of body shape and weight and, therefore, often show long-standing negative self-evaluation (Fairburn, 1997a). Being fat is associated with being worthless, unlikable, disgusting, and so on; being skinny means being attractive, successful, intelligent, happy, and so on (Vitousek & Hollon, 1990). This method of self-evaluation is remarkable because in all cases of anorexia nervosa and in most cases of bulimia nervosa, patients are not objectively overweight at all. Of course, the evaluation of a person is dependent on much more than his outward appearance alone. It is more usual to judge self-worth on the basis of performance in a variety of domains, like work, sports, friendships, relationships, and so on (Fairburn, 1997a). According to the cognitive view on the maintenance of anorexia nervosa and bulimia nervosa (Fairburn, 1997a), the overvalued ideas about the significance of body shape and weight are at the heart of the eating disorders. Self-evaluation is unduly influenced by how the subject perceives her body shape and weight. The preoccupation with food, eating, dieting, and weight control methods are supposed to be secondary to this overconcern.

The model states that binge eating follows from a particular type of dieting: intense and rigid dieting. It is postulated that eating-disordered subjects are characterized by perfectionism and black-and-white (all-or-nothing) thinking, which also becomes manifest in their way of dieting. The idea is that breaking one of their diet rules, even after a minor dietary transgression, results in the view that their diet is "totally broken," which ends up in a total loss of control and thus a binge (Fairburn, 1997a; Herman & Polivy, 1984). This is said to be accompanied by typical, disinhibiting automatic thoughts along the lines of "my day is already ruined, I might as well continue to eat" and "I'm trying not to eat. If I eat anyway, I might just as well continue to eat," reflecting their perfectionism (Garner, 1986). Thus, if eating-disordered subjects feel as if they have eaten too much, they consider their diet a failure for that day and eat too much the rest of the day. Disinhibiting, all-or-nothing thoughts are therefore supposed to be responsible for the onset of the binge.

The cognitive view on the maintenance of anorexia nervosa and bulimia nervosa is at the moment the most widely accepted model of eating disorders. Strikingly, considering the popularity and plausibility of the cognitive view on the maintenance of eating disorders, there is little direct empirical evidence for most of the hypotheses flowing from the model. Among other things, the model predicts that (i) subjects with eating disorders are characterized by negative self-evaluation or low levels of self-esteem, (ii) low self-esteem is closely related to the extreme concerns about body shape and weight, and (iii) long-term treatment success is related to a reduction of the overconcern about body shape and weight. Furthermore, it is predicted that (iv) a binge is caused by disinhibitive thoughts such as "my day is ruined now, I might as well continue to eat." Let us review the evidence.

The first hypothesis (subjects with eating disorders are characterized by low levels of self-esteem) has indeed been supported in diverse questionnaire and interview studies (see, e.g., Mizes & Christiano, 1995). Also a prospective study on the development of eating disorders showed that 11- and 12-year-old dieting girls with low self-esteem were at significantly greater risk of developing eating disorders at the age of 15–16 than dieting girls with normal and high self-esteem (Button, Sonagu-Barke, Davies, & Thompson, 1996). Considering hypothesis (ii) (the low self-esteem is closely related to the overconcern about body shape and weight), questionnaire studies indicate that subjects with eating disorders perceive weight and eating as the basis of approval from others, whereas control subjects do not (Mizes & Christiano, 1995). However, self-report data on the assumed link between mental concepts have serious limitations. There is little experimental research investigating the direct link between low self-esteem and overconcern with body shape and weight. In an analog study with restrained eaters, Eldredge, Wilson, and Whaley (1990) hypothesized that highly restrained eaters experiencing failure in an achievement task would react more negatively towards their own bodies than restrained eaters who experienced success. They found that the highly restrained eaters experiencing failure did not feel worse about their bodies than the highly restrained eaters experiencing success. Others, however, did find evidence for the link between self-evaluation and body concern. It was found that activation of thoughts about eating, weight, and shape led to an increase in negative self-statements (Cooper, Clark, & Fairburn, 1993) and, the other way around, presentation of negative events involving the self led to weight and shape explanations in eating-disordered subjects (Cooper, 1997). Furthermore, a recent study from our lab (Meijboom, Jansen, Kampman, & Schouten, in press) showed that priming low self-esteem in highly restrained subjects facilitated the accessibility of subliminally presented body shape and weight words. The latter three findings support the idea that concern with body shape and weight is linked to self-esteem in eating-disordered subjects. However, much more experimental research is needed before any definite conclusions about the link, and its causal relationship, between self-esteem and overconcern with body shape and weight can be drawn. It might, for example, be an interesting enterprise to test whether priming body shape and weight words will lead to higher accessibility of (low) self-esteem stimuli. Furthermore, it is necessary to test experimentally whether reducing the overconcern about body shape and weight will increase self-esteem, whereas an activation of the overconcern about body shape and weight in normal dieters will decrease their self-esteem.

There is some evidence for hypothesis (iii) (long-term treatment success is related to a reduction of the overconcern about body shape and weight). Fairburn, Peveler, Jones, Hope, and Doll (1993) showed that the severity of concerns about shape and weight at the end of treatment were directly related to the likelihood of relapse: 9% of the subjects with the least concerns relapsed vs. 19% of those with a moderate level of concern and 75% of those with the greatest level of concern.

Considering hypothesis (iv), clinical notes indeed indicate that a binge is caused by disinhibiting thoughts such as "my day is ruined now, I might as well continue to eat." However, such clinical impressions have received little empirical support. In our laboratory, the prediction was studied in bogus taste experiments, but it could not be demonstrated that disinhibiting thoughts play a significant role in the onset of overeating (Jansen, Merckelbach, Oosterlaan, Tuiten, & van den Hout, 1988; Jansen & van den Hout, 1991). There is, however, some circumstantial evidence consistent with the idea that the activation of disinhibiting thoughts in normal dieters can elicit bingeing. In a laboratory study with high and low restrained eaters, Spencer and Fremouw (1979) manipulated their subjects' beliefs concerning the caloric content of a preload and demonstrated that the restrained eaters overate after the preload when they only *thought* they had overeaten during the preload. It was not clear, however, whether the overeaters were characterized by more disinhibitive thoughts. Whether a straightforward activation of disinhibitive thoughts elicits a binge has never been tested. A final prediction following from the hypothesis is that a reduction of disinhibitive thoughts prevents a binge. There is an experimental finding which counters this prediction. Dieters were led into temptation to eat by smelling very palatable food. Because they merely smelled the food (their diet was not broken), it was assumed that the manipulation prevented the occurrence of disinhibitive thoughts. Contrary to what the cognitive model predicts, it was found that dieters who were merely exposed to, and intensively smelled the food, but whose diets were not actually broken or threatened, overate (Jansen & van den Hout, 1991). Contrary to hypothesis (iv), the absence of disinhibiting thoughts did not prevent dieters overeating.

All in all, there is evidence that subjects with eating disorders are characterized by low self-esteem, and there is some support for the hypothesis that low self-esteem is linked to extreme concerns about body shape and weight. However, much more experimental research on the precise link between self-esteem and body shape evaluation is needed before firm conclusions can be drawn. Furthermore, there is hardly any empirical evidence for the idea that disinhibiting thoughts cause binge eating.

There have been more studies on the cognitions of subjects with eating disorders than the studies cited above (for an overview see Vitousek & Hollon, 1990). Remarkably, however, the goal of most of those studies was to verify that eating-disordered subjects show cognitive distortions concerning food, eating behavior, body shape, and weight. For example, in the modified Stroop test, it has repeatedly been found that subjects with eating disorders selectively process stimuli related to food, eating, body shape, and weight. It has also been found that they show a memory bias for fatness words (Sebastian, Williamson, & Blouin, 1996). This kind of research may be based on circular reasoning; subjects are selected for their abnormal cognitive processes concerning body shape, weight, food, and eating, and it is concluded that they are characterized by an abnormal processing of body shape, weight, food, and eating information.

6.29.9 TREATMENT

6.29.9.1 Anorexia Nervosa

Traditionally, anorexia nervosa is treated on an inpatient basis with a program to increase weight, loosely based on operant conditioning. The patients are admitted to the clinic and it is agreed that they will gain a predetermined amount of weight each week. They are prescribed lots of bed rest (so that they will burn less energy), and a number of pleasant pastimes (receiving visitors and watching television, for example) are forbidden. They can gradually earn back these pleasant pastimes by gaining the desired amount of weight. The effectiveness of treatments of this type has never been established; the clinical impression is that patients gain weight during the treatment but quickly relapse after leaving the clinic. Perhaps this is caused by the overemphasis on the sole goal of gaining weight. Anorexia nervosa consists of more than simply being considerably underweight. Its core psychopathology consists of cognitive distortions concerning body shape and weight, which probably do not change during a treatment that is solely oriented towards gaining weight.

For this reason, today many (but not all) inpatient treatment programs are much more versatile. In addition to focusing on gaining weight, the patients learn to accept their body, for example, by video confrontation, and talk about emotions. They are often given nutritional counseling and family therapy. Focus is also placed on increasing self-esteem and improving social skills (Fichter, 1995). The effectiveness of treatments of this type, however, has not been empirically confirmed.

As long as the patient's physical condition makes it possible, outpatient treatment is preferred above intramural treatment. Recently, it has been argued that patients with anorexia nervosa would, like subjects with bulimia nervosa, benefit from outpatient cognitive behavior therapy, a treatment which is focused on changing maladaptive thoughts, feelings, and behavior (Fairburn, Marcus & Wilson, 1993; Vitousek, 1995). Again, however, the effectiveness of cognitive-behavior therapy in the treatment of anorexia nervosa also remains to be established.

Antidepressants are the most commonly prescribed medications for anorexia nervosa; however, in the long run they do not appear to be effective. The reason for this ineffectiveness may be that antidepressants do not affect the morbid attitudes, beliefs, and associated behaviors which constitute the central features of the illness (Wakeling, 1995).

6.29.9.2 Bulimia Nervosa

The effectiveness of treatments for bulimia nervosa have been studied in numerous controlled studies. Cognitive-behavior therapy, based on the cognitive model of eating disorders (see Section 6.29.8.6), has been shown to be the most effective therapy. For the present, it must be the treatment of choice for bulimia nervosa. A detailed manual was developed by Chris Fairburn (see, e.g., Fairburn, 1997a) focusing on disrupted eating behavior, the cognitive distortions concerning body shape and weight, and the long-standing negative self-evaluations of subjects with eating disorders. In about twenty 50-minute sessions over 20 weeks, the patient learns to eat and think more normally. After the therapy, a reduction in binge and purge frequency of about 80% has been observed and about 55% of the patients stopped bingeing altogether (Fairburn, 1995; Wilson, 1996a). The patients also show more normal attitudes towards their body shape and weight. In one study, patients were followed for a period of six years. The long-term results are also favorable: after six years there is virtually no relapse (Fairburn et al., 1995).

Cognitive-behavior therapy for eating disorders in fact is a multicomponent treatment package including, among others, self-control techniques, self-monitoring, education, diet management, cognitive restructuring, problem-solving training, interpersonal training, and relapse prevention. A relevant question of course is: which of these treatment components are necessary to effect positive response? For researchers on eating disorders, the time is here, now to identify the effective parts of cognitive-behavior therapy as well as to identify the mechanisms of action, that is, the mechanisms by which the effective treatment parts achieve changes.

There has been one treatment that may be as effective as cognitive-behavior therapy: interpersonal psychotherapy (Fairburn, 1997b). During this short-term focal psychotherapy, little attention is paid to the eating disorder symptoms, instead the treatment focuses on the identification and modification of current interpersonal problems. In the long run, interpersonal therapy proved to be as effective as cognitive-behavior therapy. The idea is that the treatment is successful because it improves interpersonal functioning and thereby self-worth, meaning that self-evaluation is less dependent on body shape and weight, which makes dieting less necessary and so the eating disorder gradually erodes (Fairburn, 1997b). However, the assumed mechanism by which the treatment brings about change still has to be studied, and more controlled trials are needed before any firm conclusions about the robustness of the effects can be drawn.

A rather new and promising approach is the cognitive-behavioral body image therapy (Rosen, Reiter, & Orosan, 1995). Considering the fact that the severity of concerns about shape and weight at the end of treatment are related to the likelihood of relapse (Fairburn et al., 1993), it is argued that maintenance of recovery without significant body image changes will be a continuous struggle (Rosen, 1995). The body image therapy is divided into two parts: (i) cognitive restructuring, and (ii) exposure. During the cognitive part, subjects keep a body image diary in which they record situations that provoke concerns about appearance, body image beliefs, and the effect of both on mood and behavior. Irrational, dysfunctional thoughts about the body and damaging beliefs concerning self-worth are challenged and restructured. Furthermore, the patient gradually exposes herself to a hierarchy of distressing aspects of appearance, and during the exposure the goal is to change negative self-talk in nonjudgmental self-descriptions (Rosen, 1995). A further goal is to reduce or prevent body-checking behavior. Body image therapy has been shown to be effective (Rosen, 1995), but it is surprisingly infrequently applied.

Medication for bulimia nervosa has mainly focused on the use of antidepressant drugs. Considering binge frequency, the drugs establish a reduction in binge frequency of about 60% with an abstinence rate of 22% (percentage of subjects that stopped binge eating completely). However, the effects are only maintained when subjects remain on the drugs. When medication is stopped, recurrence of binge eating is frequently seen, so the maintenance of change is poor (Fairburn, Agras, & Wilson, 1992). Furthermore, it seems that the drugs do not influence attempts to diet, cognitive distortions concerning body shape and weight, nor the longstanding negative self-evaluations of subjects with bulimia nervosa. Moreover, comparative trials show that cognitive-behavior therapy is superior to medication, and a combination of medication and cognitive-behavior therapy is not convincingly more effective than cognitive-behavior therapy alone (Wilson, 1996a).

6.29.9.3 Obesity and Binge Eating Disorder

Obesity has, so far, proved to be refractory to most treatment methods (Wilson, 1994). The behavioral weight loss programs, which are focused on dieting and self-control strategies, produce short-term weight loss but are ineffective in the long run. Recently, Wilson (1996b) has argued that the narrow focus on weight loss only may no longer prove acceptable, and he proposes a change of treatment goals. He argues that treatment of the obese should focus on the enhancement of self-acceptance, predicting that increased self-acceptance of the obese might lead to more lasting changes in eating and exercise behavior.

Treatment of the binge eating disorder has been studied only minimally. Cognitive-behavior therapy appears to be partly effective for patients suffering from a binge eating disorder. Loss of weight is not achieved, but no more weight is gained, binge frequency decreases, mood improves, dissatisfaction with the body decreases, self-esteem increases, interpersonal skills improve, and marriages become more fulfilling (Smith, Marcus, & Kaye, 1992; Wilson, 1994). Binge eaters may also benefit from cognitive-behavioral self-help treatment manuals (Cooper, 1995b; Fairburn, 1995a). In a couple of studies they have proved to be an effective treatment method to combat binge eating. They can be used independently by sufferers on their own, or with guidance from a nonspecialist therapist (Fairburn, 1997a; Fairburn & Carter, 1997).

Finally, there are preliminary data pointing to cue exposure as a successful method for the treatment of binge eating (Jansen, in press; Jansen, Broekmate, & Heymans, 1992). *In vivo* exposure with response prevention is a therapy which has been successfully applied for many years in the treatment of anxiety disorders. Subjects are repeatedly exposed to the stimuli they are afraid of, and during the exposure their anxiety gradually extinguishes. From the learning model on binge eating (see Section 6.29.8.5), it follows that the urge to binge will also be extinguished during exposure to the cues which predict a binge. By repeatedly exposing patients for long periods to the stimuli that predict a binge with response prevention (eating is not allowed), the stimuli eventually lose their predictiveness. Once the stimuli are no longer predictors for a binge, there is no point in preparing the body for consumption. The preparatory physical reactions no longer occur and the urge to binge has disappeared. The data from five, largely uncontrolled and small-scale studies are promising (see Jansen, 1998).

6.29.9.4 Predictors of Treatment Outcome

An important clinical issue is whether it can be predicted who will respond to treatment. However, reliable predictors of treatment outcome have not yet been identified. In some but not all studies, weight, premorbid and paternal obesity, self-esteem, personality disorders, and binge eating have been identified as predictor variables (Wilson, 1996a). These studies show that the worst outcome is found in subjects with lower weight, higher premorbid and paternal weight, lower self-esteem at the start of the treatment, comorbid borderline personality disorders, an early onset of binge eating, and more severe binge eating. However, the data on these negative prognostic factors are not conclusive; more and better research is needed.

6.29.10 IN CONCLUSION

The eating disorders anorexia nervosa and bulimia nervosa are characterized by: (i) abnormal eating behavior, (ii) the use of unusual methods to control weight, and (iii) irrational and dysfunctional ideas about the patient's own body and weight, leading to negative self-evaluation. Because the patients feel fat and are afraid to gain weight, they continually strive to lose weight. In the case of anorexia nervosa, this results in a decrease in weight of at least 15% compared with the person's normal weight. People with bulimia nervosa usually have a normal weight, often because of binges that regularly disrupt attempts to lose weight. During binges, considerable quantities of food are consumed, and after the binge the patient vomits, uses laxatives, or starts extreme dieting. Weight control measures of this type are partly effective: the patient gains virtually no weight. However, they do not prevent some of the food from being absorbed by the body, as a result of which the patient does not lose an extreme amount of weight.

Obesity is not an eating disorder as presently defined, but a subgroup of the obese is found to fulfill the criteria of the binge eating disorder. Like subjects with bulimia nervosa, they are characterized by objective binges during which they eat a large amount of food and lose control over intake. However, contrary to subjects with bulimia nervosa, they do not engage in the characteristic compensatory purging behaviors of bulima nervosa.

It is (as yet) unknown how the eating disorders originate. A number of influential theories have been discussed here. There is evidence for a genetic component in anorexia nervosa and obesity, but not in bulimia nervosa. However, what exactly is inherited is still unknown.

The "perfect-figure" culture appears to be more of an explanation for the common dieting among women. This does not explain the origin of eating disorders because "only" a fraction of the dieters (9%) develop an eating disorder. Dieting is related to binge eating; however, their cause and effect relationship is unclear. Empirical data show that dieting is not necessarily required for binge eating to occur, and it is also clear that dieting is not sufficient for eating disorders, including binge eating, to occur.

The serotonin hypothesis offers an explanation for the isolated act of bingeing and for the coherence between eating disorders and depression. Too little serotonin in the brain is said to result in a virtually uncontrollable craving for carbohydrates and low mood. Eating an excessive amount of carbohydrate is said to restore the serotonin level in the brain and, as a type of "self-medication," to improve mood. Empirical findings suggest that patients with bulimia nervosa do in fact have a brain serotonin deficit. However, other psychological disorders may also be accompanied by a lack of serotonin. Moreover, it has been repeatedly shown that the food patients with bulimia nervosa consume during a binge does not contain more carbohydrates than either the food they consume between binges or the food consumed by a normal control group, findings which do not support the self-medication hypothesis.

Various experimental findings suggest that overeating is a learned behavior. Predictors or cues of excessive eating trigger a craving for food for as long as they continue to predict a binge, meaning as long as they are systematically followed by excessive food consumption. They will always trigger a physical preparatory response which is experienced as craving or an urge to eat. The model is confirmed *post hoc* by a variety of findings, but there is no direct empirical evidence that supports this theory on the origin of binges.

Irrational cognitions concerning one's body shape, weight, eating, and food are characteristic for patients with anorexia and bulimia nervosa. The precise role they play in the etiology and maintenance of the eating disorders is, however, as yet unknown. In terms of the proposed cognitive origin of binge eating, it appears at this time that binges do not automatically follow irrational disinhibiting thoughts, for example, "my day is ruined anyway, I may as well continue to eat."

Despite the fact that little is known about the exact causes of eating disorders, bulimia nervosa can be effectively treated. Cognitive behavioral therapies are the most successful methods. They have a behavioral and a cognitive component; the focus is on both learning to eat normally and changing irrational thinking (about body shape and weight as well as food intake). New cognitive-behavioral approaches such as the exposure to binge provoking cues as well as the exposure to appearance, are promising and need to be studied further. The treatment of obesity is disappointing; most treatment methods are ineffective in the long run. Obese binge eaters may benefit from cognitive-behavior therapy; although weight loss is not achieved, weight gain is prevented, binge frequency decreases, and well-being improves. Finally, less is known about the effectiveness of treatments for anorexia nervosa: unfortunately, to date, virtually no properly controlled studies have been performed.

7.01.1 INTRODUCTION

Understanding the normal physiological changes associated with aging is of essential importance to clinical psychologists who work with the elderly. Issues related to depression, anxiety, and other psychological disorders are seen from new perspectives when interpreted in terms of the changes within the body that older clients are likely to experience. Of particular importance is the necessity of distinguishing between the processes of normal aging and alterations in functioning that are the result of specific diseases. Although it is true that older individuals are at heightened risk of developing chronic health problems such as arthritis, cardiovascular disease, cancer, and diabetes, these are diseases rather than normal age-related changes. Clinicians should be aware that they need to persist in the treatment of an elderly client rather than assume that the symptoms of chronic disease represent inevitable losses due to aging.

After reading this chapter, it should be clear that the physical changes associated with the aging process are complex, multifaceted, and multidirectional. Individuals age in their own unique ways, due to their genetic inheritance and lifestyle choices. Clinicians can be of tremendous help to an older person by being aware of expectable age-related changes that affect the aging population as a whole but also by planning interventions that take into account the individual's unique characteristics, life history, and resources.

In general, with regard to physical functioning, it is beneficial to advocate the "use it or lose it" principle; that is, the individual maximizes functioning by maintaining maximum levels of activity. This philosophy gives the clinician concrete tools to design treatment plans and helps to communicate a sense of optimism rather than hopelessness about aging. Furthermore, this approach often results in demonstrable gains in the older individual's daily functioning. However, the clinician is best advised to tailor the application of this principle to the client's preferences, lifestyle, and resources. It is of little help to prescribe an exercise regimen for an individual who has no access to supervised exercise facilities, has never had an interest in exercise, and who cannot afford even the proper pair of sneakers. Apart from such restrictions, however, clinicians may expect to encounter resistance of a different nature when proposing lifestyle changes to older clients. Those who have incorporated into their own identities the belief that there is in fact nothing they can do to alter their own aging will not be led by even the most effective clinician down the activity path unless this resistance can be approached and sensitively overcome. Therefore, in this chapter, a perspective incorporating the notion of identity will be discussed in regard to physical changes. With this perspective, clinicians can target interventions that take into account the ways that older individuals incorporate views about aging into their identities.

7.01.2 IDENTITY AND PHYSICAL CHANGES IN LATER LIFE

7.01.2.1 Identity Processes

The construct of identity has been used in the area of adult development to refer to the individual's sense of self over time. It is conceptualized as incorporating various content areas, including physical functioning, cognition, social relationships, and experiences in the world. In this model (Whitbourne, 1986, 1996a), identity is theorized to form an organizing schema through which the individual's experiences are interpreted. The affective content of identity, for psychologically healthy adults, takes the positive self-referential form encapsulated in the expression "I am a competent, loving, and good person;" that is, competent at work, loving in family life, and good in the sense of being morally and ethically righteous. In this model, such self-attributions are seen as contributing to the individual's emotional well-being. The developmental imperative for normal, nondepressed adults to regard themselves as having these qualities may be seen as providing a driving force in development in the adult years.

The individual's experiences, both past and present, are postulated to relate to identity through processes of assimilation and accommodation. Identity assimilation is defined as the interpretation of life events relevant to the self in terms of the cognitive and affective schemas that are incorporated in identity. The events and experiences to which the assimilation function applies can include major life events, cumulative interactions with the environment over time, or minor incidents that can have a potential impact on identity. Each type of experience can have different meanings depending on the nature of the individual's current self-conceptualizations in identity. The process of identity accommodation, by contrast, involves changing identity in response to identity-relevant experiences. An event that reflects unfavorably on identity is likely to be processed first through assimilation and, only after such efforts prove unsatisfactory, will identity accommodation follow (Brandtstadter & Renner, 1990). As a general principle, it is theorized that a healthy state of emotional adaptation involves a balance or equilibrium between the two identity processes so that the individual maintains a sense of consistency over time but is able to change when there are large discrepancies between the self and experiences (Kiecolt, 1994).

The aging process is a constant challenge to the maintenance of a stable sense of identity over time. Events caused by physical aging are qualitatively different from other experiences that are of a more transitory or fleeting nature. An unpleasant encounter in a chance meeting with a stranger that reflects unfavorably upon one's social identity will fade through time as it is dismissed through identity assimilation as lacking direct personal relevance. Aging, however, is a process that does not fade with time but may in fact grow with importance as the individual must find ways to integrate age-related changes into identity throughout adulthood.

7.01.2.2 A Multiple Threshold Model

Integrating these factors into a comprehensive framework is a "multiple threshold model" of aging (Whitbourne, 1996a, 1996b), that relates age changes to identity, coping processes, adaptational outcomes, and age-related control behaviors. The term "threshold" in this model refers to the point at which an age-related change is recognized by the individual. Before this threshold is reached, the individual does not think of the self as "aging" or "old," or even perhaps as having the real potential to be "aging" or "old." After crossing the threshold, the individual recognizes the possibility that functions may be lost through aging (or disease), and begins to accommodate to this possibility by changing identity accordingly.

The term "multiple" in this model refers to the fact that the aging process involves potentially every system in the body, so that there is in actuality no single threshold leading to the view of the self as aging. The individual may feel "old" in one domain of functioning, such as in the area of mobility, but feel "not old," "middle-aged," or possibly "young" in other domains, such as in the area of sensory acuity or intellectual functioning. Whether a threshold is crossed depends in part on the actual nature of the aging process and whether it has affected a particular area of functioning. However, it is also the case that individuals vary widely in the areas of functioning that they value. Mobility may not be as important to an individual whose major source of pleasure is derived from sedentary reading activities. Changes in the area of mobility will not have as much relevance to the individual's direct adaptation to the environment or to identity as would be the case for losses in vision or memory. In the multiple threshold model, it is assumed that changes in areas important to adaptation and competence have the greatest potential for affecting identity.

Not only are changes in central functions likely to have a greater impact on adaptation and identity, but it is possible to assume further that changes in these functions are watched for most carefully by the individual and early signs of age-related changes will be noticed in these areas. For example, the individual who takes great pride in a full and vibrant head of hair will be on the lookout for gray hairs and thinning, and the individual who values intellectual skills will scrutinize performance on activities involving memory for signs of deterioration. The increased vigilance for areas of functioning central to identity will theoretically heighten the impact of age changes.

On the other hand, with increased vigilance may come increased motivation to take advantage of control activities that reduce the impact of aging. The adult who values being in peak physical shape will work devotedly each day to avoid loss of muscle strength and aerobic capacity. Having valued these qualities, he or she will be more likely to hold onto them into old age. This situation presents a double-edged sword, in which heightened vigilance leads to behavior that offsets the aging process, thus reducing the dreaded outcomes, but also leads the individual to become acutely sensitive to signs that loss has occurred. It may be in this situation, then, that identity accommodation becomes important. The individual who recognizes that he or she is aging is less likely to become discouraged and frustrated at evidence that certain age-related changes cannot be completely reversed. The assimilative individual who desperately attempts to hang onto a youthful identity has the potential to be demolished when an event occurs that makes it abundantly clear that the aging process has taken its inevitable toll.

The multiple threshold concept is most easily viewed as a set of linear processes, with the outcome of passing through a threshold an alteration in the individual's level of well-being. The process is, however, cyclical. Each time a threshold is passed, the individual's identity has the potential to be altered through identity accommodation. When this happens, the crossing of the threshold serves as an event relevant to the self that becomes integrated into identity. The resulting change in identity then alters the individual's subsequent vigilance regarding future age-related in changes in other areas of functioning and the behaviors relevant to the threshold just crossed.

7.01.2.3 Physical Identity and Aging

The substantive content of identity incorporates the domains of physical, psychological, and social functioning. Within the domain of physical functioning are the attributes of appearance, competence, and health (Whitbourne & Primus, 1996). Physical identity may be regarded as one of the fundamental, yet overlooked, areas within psychological gerontology. For example, in a preliminary test of the multiple threshold model, it was found that the aspect of physical functioning in particular that seems to trigger the crossing of a threshold with regard to aging is the recognition of loss of physical competence, an area that is generally not given a great deal of attention by clinicians (Whitbourne, 1996b).

Individuals who use identity assimilation tend to deny as much as possible the importance of age-related changes in valued aspects of physical functioning. For these individuals, it might be speculated that changes in functioning that are related to age are not acknowledged as a result of the aging process, but instead are attributed to transitory states of health or health-related behaviors. This type of denial may be seen as an effort to preserve and protect the individual's sense of the self as competent and consistent over time.

Those older adults who rely more or less exclusively on identity accommodation overreact to small events or experiences and draw overly broad and sweeping conclusions from one instance or situation. With regard to aging, they may conclude prematurely that they are "over the hill" and fail to take preventative actions (Woodward & Wallston, 1987) because they adopt the self-image of being too weak or feeble to continue to maintain their participation in activities that were formerly rewarding to them (Janelli, 1993). As a result, they can become unduly depressed and hopeless (Parmalee, Katz, & Lawton, 1991). In a test of the multiple threshold model (Whitbourne, 1996b), identity accommodation was found to predict awareness of age-related physical changes. Thus, individuals who are highly responsive to their experiences and do not have a firm sense of self are more likely to be sensitive to the effects of normal aging on their bodies. Greater sensitivity to age-related changes, in turn, appears to be predictive of lower self-esteem.

A balanced approach to adapting to age-related changes in valued aspects of physical functioning involves taking precautions and attempting to preserve functions for as long as possible, and adapting to them when they occur by finding ways to compensate for losses. The individual may find a compromise between assimilation and accommodation by recognizing the reailty of aging, but not letting this knowledge interfere with daily functioning or future plans. There may be emotional costs involved in the recognition of impending losses, but individuals who maintain a balanced approach rebound from setbacks with renewed vigor and optimism (Labouvie-Vief, Hakim-Lawson, & Hobart, 1987; Ryff, 1989).

With this model as a backdrop, research on the physical aspects of aging will now be summarized. The concepts of the multiple threshold model and the identity processes of assimilation and accommodation will be used as the basis for suggesting clinical implications. The underlying assumption is not that the aging process must or should be slowed, but that the individual's adaptation to the aging process can be maximized by working with the assimilative or accommodative functions of identity. Ultimately, the value of these interventions can be measured in terms of improved physical health and in terms of an improved or perhaps more realistic outlook on the part of the individual toward the aging process.

7.01.3 THE EFFECTS OF AGE ON APPEARANCE AND MOBILITY

7.01.3.1 Skin

7.01.3.1.1 Age changes

A variety of changes contribute to the phenomena of wrinkling and sagging, the most apparent age-related effects on the skin. The epidermis, the outer layer of the skin, becomes flattened (Kligman, Grove, & Bolin, 1985), and as cells in the epidermis are replaced through cell renewal processes, their patterns become less organized and their arrangment less regular. These changes at the microscopic level are reflected in visible changes of the geometric furrows visible on the surface of exposed areas of the skin (Lavker, Kwong, & Kligman, 1980). Wrinkling and sagging can be explained in large part by changes in the middle, dermal layer of the skin, notably a decrease in the connective tissue collagen (Kligman et al., 1985). Elastin fibers become more brittle so that the ability of the skin to conform to movement of the bones is compromised. The subcutaneous fat on the limbs decreases and instead collects in areas of fatty deposits, such as around the waist and hips. A decrease in muscle mass, as will be discussed later, further adds to the loss of firmness in the skin's appearance.

There are also significant changes in the sweat and oil-producing glands within the dermis that maintain body temperature and lubricate the skin surface (Bolin & Pratt, 1989; Kurban & Bhawan, 1990). In areas such as the palms and underarms, the sweat glands become less active. The sebaceous glands that lubricate the skin with their secretions diminish in activity, and consequently the skin becomes rougher, dryer, and more vulnerable to surface damage. These changes lead to heightened risk of medical problems such as dermatitis (Grove, 1989) and pruritis (excessive itching), as well as to general discomfort (Kligman, 1989).

Age-related alterations also occur in the coloring of the skin. There are fewer melanocytes, and those that remain develop irregular areas of dark pigmentation. Under the skin surface, capillaries and small arteries become dilated, creating small irregular colored lines. Varicose veins may also form, creating an uneven surface of knotty, bluish, and cordlike irregularities. The loss of capillaries means that fair-skinned people look paler, and in general the blood vessels and bones can be seen more easily under what is a more transparent skin surface.

7.01.3.1.2 Clinical implications

Age-related changes in the skin and skin-related structures alter the skin's protective functions as well as its appearance. There is less insulation provided against extremes of temperature, and less of a barrier against environmental agents that can irritate the skin and cause dermatitis (Grove, 1989). Even if the individual is not particularly concerned about the effects of age on appearance, these changes in comfort level can trigger the crossing of an aging threshold. However, for many individuals, particularly in middle age (Whitbourne, 1996a, 1996b), age changes in the skin that lead to wrinkling are very noticeable and can have an impact on the individual's identity. In particular, comparisons of present appearance with pictures or memories of early adulthood can trigger identity accommodation in a negative way to older people who valued their youthful image (Fenske & Albers, 1990; Kleinsmith & Perricone, 1989)

Having crossed this threshold in terms of appearance, there are many steps that older individuals can take to slow, compensate for, or correct the changes in appearance caused by aging of the skin. The primary method of prevention is for fair-skinned people to avoid direct exposure to the sun and to use sunblocks when exposure cannot be avoided (Gilchrest, 1989). There are also many ways for the individual to compensate for age-related changes in the skin once they have become manifest. To counteract the fragility, sensitivity, and dryness of the skin, the individual can use sunscreens, emollients, and fragrance-free cosmetics (O'Donoghue, 1991). If a client raises concerns about these aspects of appearance, interventions here, as with hair color (see below), must attempt to strike a judicious balance between intrusiveness into matters of personal taste and the concerns of preventive practice.

7.01.3.2 Hair

7.01.3.2.1 Age changes

With increasing age in adulthood, for men and women, the hair on the head and body loses pigmentation and takes on a white appearance due to a decrease in melanin production in the hair follicles. The rate at which hair color changes varies from person to person due to variations in the timing of onset and rate of melanin production decrease across the surface of the scalp. Interestingly, although gray hair is thought to be a universal feature of aging, the degree of hair grayness is not as reliable an indicator of a person's age as is the extent to which hair on the body (axillary and pubic) has turned gray (Kenney, 1989).

Gradual and general thinning of scalp hair occurs in both sexes over the years of adulthood, although loss of hair is popularly regarded as a concern of men. Hair loss results from destruction or regression of the germ centers that produce the hair follicles underneath the skin surface. However, in men with pattern baldness, the hair follicles do not actually die but change the type of hair they produce from coarse terminal hair to fine translucent vellus hair. Men may also experience thinning of the hairs in their whiskers, and a growth of coarse hair on the eyebrows and inside the ear. Patches of coarse terminal hair may develop on the face of women, particularly around the chin.

7.01.3.2.2 Clinical implications

As is true for wrinkles, the threshold for age-related changes in the hair, at least for graying, appears to be crossed at some point in the 30s or 40s (Whitbourne, 1996b). Compared to wrinkles, gray hairs are relatively easy to detect; however, unlike wrinkles, gray hairs can be returned to virtually their original state through the use of hair dye. Changes in hair thickness, however, are not so easily reversed. The desire to disguise or stop the apparent signs of aging through surgery or the wearing of hairpieces is widespread, as is evident in the many advertisements for hair loss replacement processes.

There are many ways in which clinical intervention can be of use when changes in hair amount and color becomes a concern. Apart from providing information about commercial products that can be used if the individual chooses to try to combat the aging process, interventions can focus on ways the individual can learn to reframe age changes in the hair's appearance, particularly with regard to hair thinning, in a manner that allows for a balance between identity assimilation and accommodation. Since there are no practical implications of hair loss or hair graying, interventions in this area can be entirely at the discretion of the client and clinician. Unlike cardiovascular functioning, in which denial of age-related changes can prove fatal, the denial of changes in the hair does not have severe health consequences. The only exception is when the individual is at risk of ostracism or ridicule by others due to inappropriate attempts to maintain what he or she thinks is a youthful head of hair. In these cases, the accommodation process may need to be brought to bear on the situation so that the individual can accept that patch of skin on the top of the head or can find a hair dye that does not attempt to recreate the look of a 20-year-old. Of course, these issues quickly become matters of taste and preference, and short of major concerns or problems, should ultimately be left to the individual's discretion.

7.01.3.3 Body Build

7.01.3.3.1 Age changes

It is a well-established fact that over the course of adulthood there is a consistent pattern of a reduction in standing height, occurring at a greater rate after the 50s and particularly pronounced in women (Shephard, 1978). The major cause is loss of bone mineral content in the vertebrae, which leads them to collapse and cause compression in the length of the spine (Garn, 1975). Changes in the joints and flattening of the arches of the feet can further contribute to height loss (Kenney, 1989).

Total body weight increases from the 20s until the mid-50s, after which total body weight declines. Most of the weight gain in middle adulthood is due to an accumulation of body fat, particularly around the waist and hips. The weight loss that occurs in the later years of adulthood is not due to a slimming of the torso but to a loss of lean body mass consisting of muscle and bone (Chien et al., 1975; Ellis, Shukla, Cohn, & Pierson, 1974). Consequently, very old adults may have very thin extremities but fatty areas in the chin, waist, and hips. Middle-aged and older women are particularly likely to experience this accumulation of body fat around the torso, with a gain of abdominal girth amounting to 25–35% across the adult years compared to 6–16% for men over a comparable time period (Shephard, 1978). However, contemporary changes in lifestyle and improved nutrition may be altering this trend, with current cohorts of older women showing a decrease rather than an increase in body fat (Rico, Revilla, Hernandez, Gonzalez-Riola, & Villa, 1993).

7.01.3.3.2 Clinical implications

Changes in body fat that lead to the appearance of a sagging or heavier body shape can result in increased identification of the self as moving away from the figure of youth. The development of "middle-aged spread" is one of the first occurrences to trigger identity accommodation of the self as aging, perhaps even before the first gray hairs have sprouted. Indeed, awareness of changes in body composition can occur surprisingly early in adulthood, perhaps by the 30s (Whitbourne, 1996b).

Fortunately, the crossing of the body fat threshold may be readily compensated, and before the individual gives up on trying to slow down this particular process, there are many activities that the clinician can promote if this is an area of concern for the individual. It is well established that participation in active sports and exercise activity can offset the deleterious effects of aging on body fat accumulation. For instance, endurance athletes do not gain weight and they maintain their muscular physiques throughout adulthood for as long as they continue to train (Suominen, Heikkinen, Parkatti, Forsberg, & Kiiskinen, 1977). Participation in exercise training programs can even be of value for middle-aged and elderly adults who were sedentary throughout their lives. By engaging in vigorous walking, jogging, or cycling for 30–60 minutes a day for 3–4 days a week, the sedentary adult can expect to achieve positive results in a period as short as 10–20 weeks (Whitbourne, 1996a). Furthermore, the same activities that a middle-aged person might engage in to combat body fat changes can also have very positive cardiovascular and general health benefits. Thus, vanity might actually serve a protective function in this area.

Changes in body height are less easily compensated, but identity processes are also less likely to be engaged in this area unless the individual has had concerns about height from the early years and on. Clinical interventions here may focus on the maintenance of bone strength through weight resistance training and although these activities might not have an enhancing effect on height, they can be very important in promoting mobility (see below), another major concern for many older adults.

7.01.3.4 Mobility

7.01.3.4.1 Age changes

The individual's ability to move around in the physical environment is a function of the integrity of the muscles, bones, joints between the bones, tendons and ligaments that connect muscle to bone, and contractility of flexor and extensor muscles. Mobility changes in important ways over the course of the adult years such that movement becomes more difficult, more painful, and often less effective for the older adult.

Between ages 40–70 years, the loss of muscle strength amounts to approximately 10–20% with more severe losses of 30–40% after ages 70 to 80 years; losses that are more pronounced in the muscles of the lower extremities (McArdle, Katch, & Katch, 1991). This pattern of diminishing muscle strength appears to be due to atrophy of muscle fibers, particularly the "fast twitch" fibers important in developing the rapidly accelerating powerful contractions normally associated with strength. The "slow twitch" fibers involved in maintaining posture and muscular contractions over protacted periods of exertion remain constant over the adult years. The atrophy of fast-twitch fibers is thought to result from the loss of the motoneurons that activate the muscles. After the muscle fiber dies, it is replaced initially by connective tissue and in its final stages, by fat (Fiatrone & Evans, 1993). However, declines in muscle strength are not completely accounted for by loss of muscle mass, and there are other influences on age effects on muscle strength as yet to be determined (Kallman, Plato, & Tobin, 1990; Overend, Cunningham, Kramer, Lefeve, & Paterson, 1992).

There are individual variations that can lead to important deviations from such a general pattern of decline. The extent to which aging affects loss of muscle strength depends in part on which gender is being tested, the general level of activity in which the individual has typically engaged, the particular muscle group being tested, and whether the type of muscle strength being assessed is static (isometric) or dynamic.

Although the process of bone growth and remodeling continues, the overall course of bone development in adulthood is toward loss of bone strength, resulting in diminished ability of the bones to withstand mechanical pressure and to show greater vulnerability to fracture. The decrease in various measures of bone strength ranges from 5 to 12% per decade from the 20s through the 90s (McCalden, McGeough, Barker, & Court-Brown, 1993). Loss of bone strength is generally explained as a function of the loss of bone mineral content, meaning that the bone becomes increasingly porous and unable to support the loads it must bear. The extent to which bone mass decreases over the years of adulthood amounts to approximately 20–30% of total bone mineral content in women, and approximately half that amount in men (Mazess, 1982; Riggs et al., 1981). The period of maximum bone loss is between the 50s and the 70s (Sparrow, Beausoleil, Garvey, Rozner, & Silbert, 1982). The explanation of the underlying process that causes loss of bone mineral content is that the rate of resorption exceeds that of new bone growth in later adulthood, giving a net result of a reduction in bone mass (Sherman et al., 1992). In part, bone density and the loss of bone mass in the later years of adulthood may be a function of genetic factors (Dargent & Breart, 1993; Kelly et al., 1993). Lifestyle also seems to play a role, however, including factors such as physical activity, smoking, alcohol use, and diet which can account for 50–60% of the variation in bone density (Krall & Dawson-Hughes, 1993). There are also hormonal influences on bone mass, as indicated by the observation that bone mineral loss in women proceeds at a higher rate in postmenopausal women who are no longer producing estrogen in monthly cycles (Nuti & Martini, 1993).

Although the aging of joints is most commonly associated with the later years of life, degenerative processes that reduce the functional efficiency of the joints begin even before the individual reaches skeletal maturity. Restrictions of movement and discomfort are therefore a potential problem for adults of any age, but they occur with increasing frequency as age progresses. The decline in joint functioning can be accounted for by age losses in virtually every structural component of the joint. Starting in the 20s and 30s, the arterial cartilage begins to thin, fray, shred, and crack (Adrian, 1981). Unprotected by cartilage, the underlying bone eventually begins to wear away. At the same time, outgrowths of cartilage develop and these interfere with the smooth movement of the joint. Age-related weakening of the muscles further contributes to restrictions in range of movement due to changes in the joints themselves (Vandervoort et al., 1992). Changes at the cellular level in the structure of collagen and elastin comparable to those that occur in the dermis are thought to contribute to loss of flexibility, strength, and resiliency of connective tissue. Diminished efficiency of circulation may contribute further to deteriorative changes. Since the cartilage receives little vascular supply to begin with, any reductions in adulthood due to aging or arterial disease will further reduce its reparative ability. Furthermore, the joints are subjected to an extreme amount of trauma throughout life, including the strains and sprains encountered during everyday activities and strenuous exercise, activities that further contribute to their deterioration.

7.01.3.4.2 Clinical implications

For many individuals, thresholds of aging become painfully crossed with each newly-discovered joint ache or mobility restriction, sometimes beginning in the 40s (Whitbourne, 1996b). Changes in the structures that support movement have many pervasive effects on the individual's life, resulting in restrictions in activity and pain which can interfere with the individual's psychological adaptation and sense of well-being (Hughes, Edelman, Singer, & Chang, 1993). In part, the effects of mobility loss can be attributed to the enforced reliance on others that is created, leading to other deleterious processes such as being treated like a dependent child (Whitbourne & Wills, 1993).

One of the most serious outcomes of reduced muscle strength, bone strength, and joint mobility is the heightened susceptibility of older individuals, particularly women, to falls (Dargent & Breart, 1993; Lord, Clark, & Webster, 1991). If a broken hip results, the individual is more likely to suffer long-term disability and dependency (Roberto, 1992). Unfortunately, individuals might overreact to falls by developing a "fear of falling" (Downton & Andrews, 1990) or lowered sense of self-efficacy regarding the ability to avoid a fall (Tinetti & Powell, 1993). As a result, they become less stable on their feet and avoid physical activities that might benefit their strength and stability. Understandably, these individuals are vulnerable to feelings of depression and anxiety. Other adults may react to falls through identity assimilation, by repressing their occurrence (Wright, Aizenstein, Vogler, Rowe, & Miller, 1990), which might maintain their sense of self-efficacy but place them at risk of further serious injury.

This summary of age-related changes in mobility describes a fairly downhill process, but there are many interventions clinicians can pursue that will have practical advantages. As has been mentioned already, it is important to structure an intervention around the nature of the individual's identity processes, particularly as balanced against the individual's actual age-related losses and possiblities for compensation. Given such an assessment, older individuals can be encouraged to participate in a variety of physical exercises that can prove to be extremely helpful in maintaining or restoring mobility. A regular program of exercise can help the middle-aged and older adult compensate substantially for the loss of muscle fibers. Although there is nothing that can be done to stop the loss of muscle cells, the remaining fibers can be strengthened and work efficiency increased through exercise training even in persons as old as 90 years (Fiatrone et al., 1990). Inactivity can accelerate the loss of muscle strength, and the same is true of bone loss. Older individuals can also benefit from resistance training exercises that, within limits, increase the stress placed upon the bone (Dalsky et al. 1988; Rikli & McManis, 1990; Smith, 1981). Although degenerative changes in the joints are not reversible, it is possible for older individuals to benefit from exercise training, particularly if it is oriented toward promoting flexibility (Jirovec, 1991), strengthening the muscles that support the joints, increasing the circulation of blood to the joints thereby promoting the repair of injured tissues (Brooks & Fahey, 1984), and decreasing the risk of injury (Stamford, 1988).

7.01.4 THE EFFECTS OF AGE ON VITAL FUNCTIONS

7.01.4.1 Cardiovascular System

7.01.4.1.1 Age changes

The aging process results in serious limitations of the heart's functional requirement to pump blood continuously through the circulatory system at a rate that adequately perfuses the body's cells. Although a distinct entity in terms of underlying processes, fatal cardiovascular diseases do become more probable with advancing age in adulthood. These diseases can have widespread effects on daily life in addition to providing constant sources of reminders of the individual's mortality. For example, the chest pains associated with angina, a chronic cardiac illness, are not only uncomfortable but provide clear warning signals of the heart's impending failure.

The reduction in the heart's pumping capacity is due to a variety of changes affecting the structure and function of the heart muscle walls, particularly the left ventricle which becomes progressively thicker with each decade in adulthood and less elastic (Kitzman, Scholz, Hagen, Ilstrup, & Edwards 1988; Kitzman & Edwards, 1990) as the number of myocardial cells decreases and the remaining cells become hypertrophied (Olivetti, Melissari, Capasso, & Anversa, 1991). The decreased capacity of the ventricle walls to expand results in a reduced and delayed filling of the left ventricle and the ejection of less blood into the aorta. The cardiac muscle also becomes less responsive to the neural stimulation of the "pacemaker" cells in the heart that initiate each contraction (Montamat & Davies 1989; Schulman & Gerstenblith, 1989).

Effects of aging on the arteries further compromise the system's ability to distribute blood to the body's cells. Although it is difficult to separate the effects of aging from those of atherosclerosis (a disease in which the arteries become rigid and narrowed by fatty accumulation), the aging process itself appears to cause changes in the aorta and arteries (Shimojo, Tsuda, Iwasaka, & Inada, 1991). The wall of the aorta becomes less flexible, so that the blood leaving the left ventricle of the heart is faced by more resistance and cannot travel as far. The walls of the arteries throughout the body become thicker and less flexible. Impedence of blood flow through the arteries is further augmented by the accumulation of lipids in the blood (Heiss et al., 1980).

Although age-related changes in the heart and arteries reduce the amount of blood available to the cells of the body, under normal conditions these changes are not particularly pronounced or noticable. The effects of aging of the circulatory system are most apparent while the individual is engaging in aerobic exercise, when there is a reduction both in maximum oxygen consumption (aerobic capacity) and the maximum attainable heart rate (Lakatta, 1987; Morley & Reese, 1989). Aerobic capacity decreases in a linear fashion throughout the adult years, so that the average 65-year-old individual has 30–40% of the aerobic capacity of the young adult (McArdle et al., 1991). Other functional variables decrease to a commensurate degree, such as the amount of blood pumped at each beat of the heart (Weisfeldt & Gerstenblith, 1986), and the cardiac output per minute. These decreases in the functional capacity of the heart mean that less oxygen reaches the muscles during exercise. Changes in the heart and arteries can also account, in part, for the observation that older individuals have higher levels of systolic and diastolic blood pressure, both at rest and during exercise.

7.01.4.1.2 Clinical implications

Although not as apparent in its effects on identity as appearance, the functioning of the cardiovascular system is an important influence on the individual's feelings of well-being and identity. The efficiency of the cardiovascular system is essential to life so that threats to the integrity of this system are perceived as highly dangerous. Awareness of reduced cardiovascular efficiency can therefore serve as reminders of one's own personal mortality.

In working with middle-aged and older adults, clinicians can turn to the wealth of research pointing to the effectiveness of exercise in slowing or reversing the effects of the aging process. The results of research on the effectiveness of exercise training have consistently revealed improved functioning in long-term endurance athletes, master athletes, exercisers, and previously sedentary adults (Whitbourne 1996a; McArdle et al., 1991). Previously sedentary adults can improve to levels that approximate the improvements achieved by younger adults (Govindasamy, Paterson, Poulin, & Cunningham 1988; Hagberg et al., 1989). Even moderate or low-intensity exercise can have beneficial effects on healthy sedentary elderly (Foster, Hume, Byrnes, Dickinson, & Chatfield 1989; Hamdorf, Withers, Penhall, & Haslam, 1992). Further, aerobic exercise training has the positive effect of lowering the heart rate and improving work load intensity and duration in submaximal exercise, (Morey et al., 1991; Poulin, Paterson, Govindasamy, & Cunningham, 1988), ultimately placing less stress upon the heart during exertion. Other benefits of exercise training are improvements in the peripheral vasculature (Blumenthal et al., 1989), lipid metabolism (Tamai et al., 1988), and blood pressure during or immediately after exertion (Webb, Poehlman, & Tonino, 1993). That exercise can have such positive effects on physical functioning in old age, even if it is begun after a lifetime of sedentary patterns, provides strong evidence in favor of the view that the rate of the aging process can be altered significantly through active lifestyle choices made by the individual.

The main advantage that exercise seems to hold as a means of retaining a higher level of cardiovascular functioning is that it provides a continued potent stimulus for the muscle cells of the heart to undergo strong contractions so that they retain or gain contractile power. The greater strength of the myocardial muscle improves the functioning of the left ventricle and as a result, more blood can be ejected from the left ventricle (Ehsani, Ogawa, Miller, Spina, & Jilka, 1991). The other advantage of exercise training is that it makes it possible for the individual to "save" energy during aerobic work that is less than maximal by fulfilling the demands of the work load but placing less stress on the heart. Because more blood is ejected with each cardiac muscle contraction, the same output of blood can be pumped per minute but at a lower heart rate. The effects of training on cardiac functioning under submaximal conditions are of interest in that these performance situations are closer to the conditions under which people exert themselves in their daily lives. Exercise training also has favorable effects on the body's performance by increasing the efficiency of metabolism in the working muscles (Meredith et al., 1989).

In addition to the advantages of exercise training for the cardiovascular system, it is well established that adults who become involved in aerobic activities experience a variety of positive effects on mood, anxiety levels, and particularly feelings of mastery and control, leading to enhanced feelings of self-esteem (Hill, Storandt, & Malley 1993; McAuley, Lox, & Duncan, 1993). Although some researchers have demonstrated there to be positive effects of exercise on cognitive functioning (Chodzko-Zajko, Schuler, Solomon, Heiul, & Ellis, 1992; Stevenson & Topp, 1990), this effect is not observed consistently (Hill et al., 1993). Nevertheless, it appears clear that older adults who enter exercise training programs "feel better," and this improvement in mood can be clinically useful for many aging clients.

A great deal has been written in the area of behavioral medicine on strategies for increasing the compliance of cardiac patients with dietary and exercise controls over the progress of their disease. In terms of the normal aging process, similar interventions might be suggested. Those individuals who deny the effects of aging through identity assimilation must be brought to recognize that they will run real risks to their lives if they either fail to engage in preventative behaviors or engage in strenuous activities without proper supervision or training. In contrast, middle-aged and older individuals who overreact to age changes in what they have heard about cardiovascular functioning, or perhaps to the appearance of slight symptoms, need to be given assurance that they can nevertheless continue to engage in exercise activities and that, indeed, such activities are necessary for the prevention of further and more serious health limitations.

7.01.4.2 Respiratory System

7.01.4.2.1 Age changes

The airways in the respiratory system permit gas exchange between the blood and air, making it possible for the body's cells to receive support for their metabolic activities. Aging's primary effect is to reduce the quality of gas exchange in the lungs so that less oxygen from the outside air reaches the blood (Kenney, 1989). Aging also reduces vital capacity, the amount of air that is moved into and out of the lungs at maximal levels of exertion (Reddon, 1981), and forced expiratory volume, the amount of air that can be breathed out during a short amount of time (Smith, Cunningham, Patterson, Rechnitzer, & Koval, 1992). These reductions in respiratory functioning result from changes in pulmonary structures such that the airways, and particularly lung tissue, lose the elastic ability to resist expansion as they fill with air. The changes in lung structures that account for decreased elastic recoil and increased compliance are alterations in the composition and structure of the elastin and collagen composition of lung tissue (Brandstetter & Kazemi, 1983; D'Errico et al., 1989). Increased rigidity of the chest wall further lower the lung's ability to be fully compressed during expiration and expanded during inspiration (Mahler, Rossiello, & Lohe, 1986). These changes mean that less than the maximal amount of air can be brought into and out of the lungs, particularly under conditions of exertion (Teramoto, Fukuchi, Nagase, Matsuse, & Orimo, 1995). The greater rigidity of the chest wall also increases the amount of work that must be performed by the respiratory muscles during the inspiratory and expiratory phases of the ventilation cycle.

7.01.4.2.2 Clinical implications

Age changes in respiration can lead to feelings of dyspnea and fatigue associated with exertion, sensations that can approach the intensity of a panic attack. Adding to age effects on cardiovascular functioning, changes in the respiratory system can lead the aging individual to avoid strenuous activities, a consequence that further impairs the individual's cardiovascular and respiratory efficiency. Because both of these functions are so crucial to life, and because shortness of breath is so frightening, the individual might conclude prematurely that death is around the corner.

The effects of exercise training on respiratory functioning are encouraging (Blumenthal et al., 1989) but the specific effects of exercise on respiratory functioning are not as dramatic as the effects on the cardiovascular system. Equally, if not more, beneficial to the respiratory function is the avoidance of cigarette smoking (Hermanson, Omenn, & Kronmal, 1988).

Taking these factors into account, clinicians may wish to treat instances of dyspnea leading to panic as instances of overaccommodation, in which the individual may be brought to a more balanced state through recognizing the fact that some age-related changes in breathing capacity are in fact inevitable. On the other hand, for individuals who are using identity assimilation to deny the importance of factors that impede respiratory efficiency, notably cigarette smoking, steps need to be taken to increase identity accommodation and the recognition that this behavior can accelerate the deleterious effects of aging on respiratory efficiency and feelings of comfort during exercise.

7.01.5 THE EFFECTS OF AGE ON REGULATORY SYSTEMS

7.01.5.1 Excretory System

7.01.5.1.1 Age changes

It has been known for years that there are significant and widespread changes in the structure of the kidneys, changes that are reflected in cross-sectional studies in impaired efficiency across adulthood on every measure of renal functioning studied. (Rowe, Shock, & DeFronzo, 1976). An early estimate of the loss of renal functions over the adult years was a figure of 6% per decade from age 20 and continuing into the 90s, a loss that exists in longitudinal studies as well (Shock, Andres, Norris, & Tobin, 1978). The cause of aging of the kidney is loss of structure and function of the basic cell of the kidney, the nephron (McLacklan, Guthrie, Anderson, & Fulker, 1977). There are also independent losses in mechanism within the kidney responsible for concentrating urine (Rowe, 1982).

Particularly challenging to the aging kidney is aerobic exercise because it diverts blood to the working skeletal muscles, and thereby causes a further reduction in the blood flow through the kidneys. Equally important, the urine concentrating mechanism begins to fail during exercise or under extreme conditions of heat when the individual begins to perspire. Fatigue, changes in body chemistry, and potentially harmful changes in bodily fluid levels occur more rapidly in the older adult who cannot conserve sodium and water adequately under these conditions.

The effects of aging on the bladder are of great importance to the individual's conscious experience of aging. Adults past the age of 65 years experience a reduction in the total amount of urine they can store before feeling a need to void, and more urine is retained in the bladder after the individual has attempted to empty it. These phenomena appear to be related to age changes in the connective tissue of the bladder causing the organ to lose its expandability and contractility somewhat like that which is seen in the lung. Furthermore, recognition of the need to void may not occur until the bladder is almost or even completely filled. This means that the individual has less or perhaps no time to reach a lavatory before leakage or spillage occurs.

The most significant effect of changes with age in the bladder is on patterns of urinary incontinence. The prevalence of incontinence among the population 60 years and older is estimated to be 19% for women and 8% for men (Herzog, Diokno, Brown, Normolle, & Brock, 1990) but can reach as high as 36% among community-dwelling elderly with dementia

(Ouslander, Zarit, Orr, & Muira, 1990). Women are more likely to suffer from stress incontinence, which refers to loss of urine at times of exertion such as when one is laughing, sneezing, lifting, or bending and is the result of weakness of the pelvic muscles. Urge incontinence, which is more prevalent in men, involves urine loss following an urge to void or lack of control over voiding with little or no warning (Diokno, Brock, Brown, & Herzog, 1986); it is related to prostatic disease or incomplete emptying of the bladder. Among the community-dwelling elderly, each of these conditions, particularly urge incontinence, is reversible and may disappear within a year or two of its initial development (Herzog et al., 1990)

7.01.5.1.2 Clinical implications

Although not insignificant in terms of the body's physiological efficiency, the aging of the kidney is unlikely to have a discernible impact on everyday functioning. However, age-related changes in the bladder are another matter, and can be important threshold phenomena (Whitbourne, 1996b). Incontinence can be highly disruptive to the older individual's everyday life, causing distress and embarrassment (Hunskaar & Vinsnes, 1991; Ouslander & Abelson 1990; Wyman, Hawkins, & Fantl, 1990). Not only do such occasions involve shame, but they feed into the association in many people's minds between "senility" and urinary incontinence. Other horrors of incontinence may also trigger overaccommodation, such as loss of independence and respect. Given the many associations to urinary continence, it would not be unreasonable to suppose that even a single episode of stress incontinence could create a threshold experience and overaccommodation. Unfortunately, advertisers prey on this vulnerability of older adults in commercials for adult diapers that suggest these changes to be expectable and unpreventable. Clinicians needs to work with older adult clients to dispel these myths.

On the positive side, once identified, incontinence is a condition that in many cases can be managed if the individual is able to learn new behavioral strategies. Through behavioral techniques, sometimes involving only very simple exercises, the problem can be held in check if not reversed (Burgio & Engel, 1990; Burns et al., 1993).

Age effects on renal functioning significantly affect the older person's ability to excrete medications, a fact that can be of great importance in a therapeutic context. When an older person is given the the same dosage of medication appropriate for a younger adult, more of the drug will remain in the bloodstream over the period of time between doses. With repeated dosages of the drug it is more likely that toxic levels will build up in the blood. Unless the dosage is adjusted to take into account this lower rate of tubular transport, drugs may have an adverse impact instead of their intended benefits (Lamy, 1988; Montgomery, 1990).

7.01.5.2 Digestive System

7.01.5.2.1 Age changes

The documented effects of aging on digestion in the empirical literature are remarkably minor compared to the lavish attention devoted by advertisers and the popular media to the supposed inefficiencies of digestive processes in older adults. One change with age that may have implications for digestive functioning is a reduction in the metabolism of certain nutrients in the stomach and small intestine, but other structures such as the esophagous, liver, pancreas, and large intestine appear to be relatively spared by the aging process (Whitbourne, 1996). More important than constipation, dyspepsia, and reduced sensory capacities for enjoying food are the beliefs that people hold as communicated through the media, the social context in which food is eaten, other physical and cognitive deficiencies, and the individual's lifelong patterns of nutrition (Costello & Moser-Veillon, 1992; Fischer & Iohson 1990; Ryan, Craig, & Finn, 1992; Wedman et al., 1991).

7.01.5.2.2 Clinical implications

Changes in the digestive system at the physiological level due to aging are not likely to propel the individual over an aging threshold (Whitbourne, 1996b). However, so many elders have been exposed to inaccurate conceptions in the media about the aging digestive system that clinicians have an important psychoeducational role to play. In the area of digestion and particularly elimination, embarrassment may lead the older individual to avoid discussions of anxiety-provoking issues that, if discussed and allayed, could ease these very uncomfortable feelings. Furthermore, questions about food intake are essential for clinicians to explore, as inadequate nutrition may lead to symptoms that mimic those of psychological or cognitive impairment disorders. Unchecked, a vicious cycle may be created, as depression can lead to loss of interest in food and food preparation (Rosenbloom & Whittington, 1993).

Another clinical issue related to digestion concerns fecal incontinence. Older adults, particularly those who overrely on identity accommodation, may associate irregularities in defecation with feared diseases and the prospects of institutionalization in later life (Holt, 1991; Wald, 1990). Older persons who believe that "senility" is an inevitable feature of aging may regard with alarm any indication that their patterns of elimination are changing, seeing in such changes a more ominous significance that can risk putting them over the threshold. The anxiety created by this concern may contribute further to gastrointestinal problems so that what originates as a temporary problem comes to have a more prolonged course. Clinicians can intervene in this process by sensitive discussion of this very personal and potentially frightening area of daily life.

7.01.5.3 Immune System

7.01.5.3.1 Age changes

There is substantial evidence of reduced immune system functioning across age groups of adults. T-cells, which destroy antigens (foreign substances that enter the body), lose effectiveness over the adult years (Bloom, 1994; Globerson, Eren, Abel, & Ben-Menahem, 1990), in part due to changes in the thymus gland. Autopsy studies have revealed that deterioration of the thymus gland begins shortly after sexual maturity is reached, so that by the time the individual is 45–50 years old, the thymus retains only 5–10% of its peak mass. As a result of these changes, there are more immature T-cells present both within the thymus gland and in the bloodstream. Other immune system cells, including natural killer (NK) cells, K cells, and macrophages, do appear to retain their functioning into old age (Bloom 1994; Kutza, Kaye, & Mwasko, 1995); however, another entire line of defenses is altered in the aging process through the reduced activity of helper T-cells, increased activity of suppresser T-cells, and the increasing development of certain autoimmune diseases.

7.01.5.3.2 Clinical implications

Investigations have been stimulated by progress in psychoneuroimmunology, a field in which the intricate connections are examined between affective states such as stress and depression, nervous system functioning, and operation of the immune system (O'Leary 1990; Vollardt, 1991). For example, elderly individuals with high levels of life stress have been found to experience lower T-cell functioning (McNaughton, Smith, Patterson, & Grant, 1990). Conversely, social support, at least among women, was found to be related positively to immune system competence measured in terms of lymphocyte numbers and response to mitogens (Thomas, Goodwin, & Goodwin, 1985). Older individuals are at least as susceptible to stress as younger adults in increases of T-suppressor cells and NK cell numbers, although not in terms of increased NK activity (Nabiloff et al., 1991). Stress also seems linked to the release of beta-endorphin, an opioid peptide released from the pituitary gland that has an analgesic effect. This process may play an important role in mediating the effects of emotions on the immune system (Antoni, 1987).

Apart from changes in the immune system that interact with psychological functioning, the lowered effectiveness of the immune system in older adults has important implications for health. The aging immune system has been linked to increased vulnerability to influenza, infections, cancer, and certain age-associated autoimmune disorders such as diabetes and possibly atherosclerosis and Alzheimer's disease. A less competent immune system can put the elderly individual at higher risk at least to certain forms of cancer and influenza (Ershler, 1990; Miller, 1993). Clearly, the development of severe health problems can have significant effects on the individual's psychological well-being.

There are many ways in which clinicians can take advantage of the potential interactions between identity and immune system functioning. The crossing of an aging threshold in any salient area of functioning, to the extent that it triggers a stressful reaction, can lead to deleterious effects on immune functioning. The individual then becomes more susceptible to immune-related conditions, further accentuating the effects of crossing the threshold. Overassimilation may have some beneficial aspects, in this regard, if the individual is not placed at risk by ignoring important physical changes.

7.01.6 AGE CHANGES IN THE REPRODUCTIVE SYSTEM AND SEXUALITY

7.01.6.1 Female Reproductive System

Throughout her 40s, a woman's reproductive capacity becomes gradually reduced until, by the age of 50–55 years, it ceases altogether. Associated with the ending of the monthly phases of ovulation and menstruation is a diminution of the hormones estrogen and progesterone. Other changes in sexual functioning are related to aging of the tissues in other bodily systems. For example, sagging of the breasts and torso results from decreased skin elasticity. Subcutaneous fat accumulates around the waist, leading to uneven bulges. The appearance and functioning of the genital organs also change after the menopause. The pubic hair on the mons veneris and around the vulva becomes thin and coarser. The labia majora and minora become thinner and wrinkled, the skin in the vulva atrophies, and the surface cells of the vaginal wall become thin, dry, pale, and smooth. The vagina also becomes narrower and shorter. These changes are significant not only for their effects on sexual functioning but for their effects on the woman's enjoyment of sexual intercourse. The older woman may experience discomfort during intercourse due to changes in the vagina and vulva, and the rhythmic contractions of the uterus during orgasm may become painful.

Despite changes in the reproductive system, the conclusion reached by Masters and Johnson (1966) in the mid 1960s is still generally accepted: that older women are limited in their sexual gratification more by their attitudes, values, and accessibility to partners than they are by physical changes involved in aging. The sexual response cycle might be slowed down somewhat in the older woman, but the possibility of achieving orgasm is not reduced.

7.01.6.2 Male Reproductive System

Just as women gradually lose reproductive capacity, men experience a climacteric of sorts in which there is a reduction in the number of viable sperm they produce due to degenerative changes in the seminiferous tubules of the testes (Harman, 1978). With increasing age, men may experience changes in the prostate gland that lead to a reduction of the volume and pressure of semen expelled during ejaculation. Age-related changes also include overgrowth or hypertrophy of the glandular and connective tissue in the parts of the prostate that surround the prostatic urethra. This condition, called benign prostatic hypertrophy, is increasingly prevalent in men past 50 years, rising to an estimated 50% of men 80 years and older. The adjacent penile urethra may become constricted due to this overgrowth, and urinary rentention may ensue. Discomfort and embarrassment may result from difficulties in urination and from the occurrence of involuntary penile erections (Masters & Johnson, 1966). If urinary retention becomes a chronic condition, kidney problems may develop, leading to more serious health threats.

A physiological index of reproductive function that has a decidedly noticeable effect on the older man's sense of his own sexuality is that of penile erectility. It is well documented that older men experience fewer nightly episodes of penile erections compared to younger males (Karacan, Willliam, Thornby, & Salis, 1975). By contrast, there are inconsistencies in the findings regarding increase in penile circumference during erection, with some decreases noted across age groups (Solnick & Birren, 1977), and in other research no age differences are observed (Schiavi & Schreiner-Engel, 1988).

As is true for aging women, there is a general slowing down in aging men of the progression through the human sexual response cycle. Compared to young adult men, orgasm is shorter, involving fewer contractions of the prostate, and ejection of a smaller amount of seminal fluid (Masters & Johnson, 1970). These findings may carry some negative implications for the aging male's sexual relations. However, the gains for the older man's ability to enjoy sexuality are also compelling. He may feel less driven toward the pressure to ejaculate, be able to prolong the period of sensual enjoyment prior to orgasm, and have the control to coordinate his pleasure cycle to correspond more to his female partner.

The main predictor of a man's pattern of sexuality in the earlier years of adulthood is by far the best predictor of his sexuality in old age (George & Weiler, 1985). The sexually active middle-aged man, given good health, has the potential to remain sexually active well into his later years.

7.01.6.3 Clinical Implications

The impact of the menopause depends heavily on how the woman interprets the significance of this transition, which may be met with relief or as a reminder of the inevitability of aging and mortality. Although the aging male is likely to be less preoccupied by his diminished (but not lost) reproductive capacity, he may also find age-related changes to have a negative impact on his enjoyment of sexual relations. He may overaccommodate to aging changes, believing that his masculine prowess has failed. Furthermore, the changes he perceives in his sexual functioning may be interpreted as movement toward deterioration and death. As is true for any man regardless of age, depression, heavy alcohol use, or late-life career pressures may also interfere with the aging male's ability to enjoy sexual relations. Difficulties in adjusting to age changes in the sexual response cycle may present a problem if the partners are unfamiliar with the fact that sexual responsivity naturally becomes altered in later adulthood. The woman may worry that she has lost her orgasmic capacity because it takes her longer to become aroused, excited, and stimulated. The aging male may be at high risk of developing symptoms of secondary (nonphysiological) impotence.

As is true of other sensitive areas of physical functioning, the clinician's responsibility in these areas is to explore in a patient and careful manner the level of concern the individual or couple may have about their functioning. Given cohort differences in attitudes toward sexuality, it is likely that the average older person finds it difficult to discuss specific details about problems in sexual functioning. The general level of anxiety associated with sexual matters can lead to heightened potential for either identity assimilation in the form of denial, or identity accommodation in the form of overreaction. Furthermore, in this area perhaps more so than in any other, it might be necessary for the clinician's own attitudes toward sexuality in the aged to become an area of personal focus and reflection before proceeding to the level of intervention.

7.01.7 THE NERVOUS SYSTEM

7.01.7.1 Central Nervous System

7.01.7.1.1 Age changes

In the central nervous system (CNS), as in the other major organ systems, changes that are due to aging alone are difficult to separate from changes that are the result of disease. Neurofibrillary tangles, amyloid plaques, and granulovacuolar degeneration are all deleterious changes observed in the brains of people with Alzheimer's disease, but are also thought to occur to a lesser extent in normal aging. There are thought to be decreases in acetylcholine levels in the hippocampus and a decline in the number of neurons in the hippocampus, but these are also well-known correlates of Alzheimer's disease. Similarly, decreased amounts of dopamine in the substantia nigra–basal ganglia pathway are regarded as age-related changes but are also observed in Parkinson's disease. It is not clear whether these losses occur normally in later life and are exaggerated in the case of disease, or whether they constitute discrete phenomena.

Keeping in mind the distinction between normal aging and disease processes, there is documentation that areas of the brain are differentially affected by neuronal loss in later adulthood. There appear to be signficiant losses of neurons from the hippocampus, the area affected by Alzheimer's disease and involved in short-term memory (Mouritzen Dam, 1979), and in the cerebellum (Hall, Miller, & Corsellis, 1975), the structure that regulates refined motor patterns. Age losses in these subcortical areas, however, are considered relatively minor compared to losses (as high as 50%) in the areas of the cerebral cortex responsible for processing sensory information, including the primary visual cortex (Devaney & Johnson, 1980), the primary somatosensory region (Henderson, Tomlinson, & Gibson, 1980), and the secondary auditory cortex which loses between one-third and one-half of its total number of neurons over the adult years (Brody, 1955; Henderson et al., 1980). Cells in the motor cortex show comparable losses of 20–50%, and these losses are thought to be a contributing factor to muscular stiffness, slowness, and joint pain (Scheibel, 1982). In contrast to these somewhat dramatic losses of neuron numbers is the pattern of relative stability in the prefrontal region of the cortex (Higatsberger, Budka, & Bernheimer, 1982; Huttenlocher, 1979). The stability of neurons in these regions of the cortex is important, as these are the parts of the nervous system involved in judgment, abstract thinking, and the ability to plan.

7.01.7.1.2 Clinical implications

Aging of the CNS has direct effects on a variety of sensory, motor, and cognitive capacities and behaviors including perception, short-term memory, fine motor coordination, and large muscle control. However, the view of the aging brain as a degenerating system does not take into account what is known about the compensatory processes of redundancy and plasticity (Buell & Coleman, 1979; Flood, Buell, Horowitz, & Coleman 1987; Flood & Coleman, 1988). The impact of these processes is most likely to occur in the association areas of the cerebral cortex, where higher order abstract thinking processes are mediated. In fact, these abilities may improve in the later years of adulthood as the individual stores more experiences into the long-term memory association areas on which decisions and judgment are based.

Furthermore, it is important to emphasize once again that there is tremendous variation among adults in the ways in which the aging process (apart from disease) affects CNS functions. Some of these functions in later adulthood are, in addition, affected by the extent to which the individual developed and used them during the adult years. Exposure to stimulation in the areas of perception, cognition, and motor activity through mental and physical exercise can influence, throughout old age, the degree to which the abilities that depend on these functions are maintained. The importance placed by the individual on mental and physical abilities contributes further to the personal meaning of age changes in any of these areas and whether a threshold is crossed in this domain.

Clinically, of course, it is essential that those working with the elderly are knowledgable about and sensitive to the symptoms of Alzheimer's disease, particularly as these differ from other forms of cognitive impairment or depression. Clinicians must also be aware of the extent to which elders fear the onset of Alzheimer's disease and interpret even minor changes in cognitive functions as signs that the end is in sight. Overaccommodation in the cognitive domain can prove extremely damaging to the older adult's identity as a sentient being, and vigilance in this area toward any signs of deterioration is likely to be high. This risk is perhaps greater than that of overassimilation, except when an individual who really does have early symptoms of Alzheimer's disease denies the memory or judgment problems that are interfering with daily life activities. Media attention to Alzheimer's disease, although positive in the sense of educating the public, may backfire in this domain, leaving many elders (and clinicians) with the erroneous impression that the disease is an inevitable outcome of the aging process.

7.01.7.2 Autonomic Nervous System

7.01.7.2.1 Age changes

Although in many aspects the autonomic nervous system (ANS) operates without significant age-related alterations throughout adulthood, there are important effects of aging on two functions served by the ANS that have a considerable impact on the individual's daily life: bodily temperature control and sleep patterns.

It is well established both through population health statistics and experimental studies that individuals over the age of 65 years have impaired adaptive responses to extremely hot and cold outside temperatures. The diminished response of the elderly to cold appears to be due to a diminished perception that the core body temperature is low, and to an impaired ability to raise core temperature when the body's peripheral temperature becomes lowered. Responses to extremes of heat are impaired due to decreased secretion by the sweat glands in the skin.

In the area of sleep regulation, older adults spend more time in bed relative to time spent asleep due to longer time taken to fall asleep, more periods of wakefulness during the night, and time spent lying awake before arising in the morning. The primary causes of sleep disturbance include sleep apnea (Ancoli-Israel & Kripke, 1991), periodic leg movements, heartburn, and frequent needs to urinate (Freidman, Bliwise, Tauke, & Salom, 1992). EEG sleep patterns show some corresponding age alterations, including a rise in Stage 1 sleep (drowsiness without actual sleep), and a large decrease in Stage 4 sleep (slow wave or heavy sleep). By the 60s and 70s, REM sleep starts to diminish as well, as do the observable behaviors associated with REM sleep.

7.01.7.2.2 Clinical implications

The knowledge gained from personal experience and media exposure that one's aging body is less adaptable to outside temperatures means that adults living in geographical areas with cold winters will restrict their outdoor activities and spend more time at home. They will also limit their outdoor exposure during the summer. Overaccommodation to the threshold experience of aging in this regard can reduce the well-being of the older adult who may feel forced to remain indoors unnecessarily even on days when the temperature would not pose a threat. Conversely, overassimilation can have deleterious effects when the older adult does not take precautions during physical exertion or when venturing out into a very hot or very cold day. Fortunately, the changes in the ANS described here occur gradually over a period of years. Consequently, there are many opportunities for the individual to learn to adjust to the effects of aging and find new behavioral accommodations as these become necessary. Clinicians can play an important role in this process through helping their clients establish a favorable balance between overreaction and denial of aging-related changes in temperature regulation.

Similarly, the function of sleep in everyday life is clearly crucial to the individual's sense of well-being and there is a strong relationship between quality of sleep and psychological symptoms (Bliwise, 1992). Given the sensitivity of sleep patterns to psychological distress, this is an area where identity–age change relationships might very profitably be discussed in therapy. Older adults who overreact through accommodation to slight sleep change patterns are perhaps the ones fated to experience the most significant changes in their ability to get a good night's sleep. They need to be given the information that a night's sleep need not consist of more than seven hours and that the longer the time spent in bed awake, the harder it will be for the individual to develop a normal nightly rhythm based on this more realistic sleep requirement. The clinician can also advise the client to avoid daytime naps and to follow good sleep habits.

7.01.8 AGE CHANGES IN SENSORY FUNCTIONING

7.01.8.1 Vision

7.01.8.1.1 Age changes

The optical structures in the eye focus light reflected from stimuli in the environment onto the sensory cells of the retina. Many, if not all, age effects on visual functions can be explained in terms of the effects of normal aging on these optical structures (Scheie & Albert, 1977). One effect of these changes is to reduce the clarity of the visual image reaching the retina. The image reaching the retina is clouded by increased density and opacity of the lens (Spector, 1982), and by the formation of opacities in the vitreous. Adding to these structural changes are changes in the retina itself, including declines in the number of photoreceptors (rods and cones) (Ordy, Brizzee, & Johnson, 1982), the accumulation of debris in the outermost layer of the retina (Marmor, 1980), and detachment of the vitreous from the surface of the retina (Scheie & Albert). The amount of light reaching the retina is diminished by the condition known as senile meiosis, reduction in the size of the pupil due to atrophy of the iris dilator (Carter, 1982).

In addition to these changes that reduce the quality of the visual image on the retina are changes in the lens that decrease its capacity to accommodate to necessary changes in focus as objects move closer or further away from the individual. In addition to becoming denser, the lens fibers become harder and less elastic (Paterson, 1979). The loss of accommodative power of the lens due to these changes is referred to as presbyopia, and it is a condition that typically requires correction between the ages of 40 to 50 years. By the age of 60 years, the lens is completely incapable of accommodating to focus on objects at close distance (Moses, 1981). The lens also becomes yellowed due to an accumulation of yellow pigment, and as a result the older adult is less able to discriminate colors in the green–blue–violet end of the spectrum (Mancil & Owsley, 1988).

These structural changes in the eye result in altered refractive power leading to hypermetropia (farsightedness), a condition that cannot be compensated by greater focusing of the lens due to presbyopia. There is a reduction in visual acuity which is especially severe at low levels of illumination, such as driving at night, and when tracking moving objects (Panek, Barrett, Sterns, & Alexander, 1977; Richards, 1977). Dark adaptation is reduced so that older adults have greater difficulty adjusting to movement from bright to dim lighting, and have lower absolute levels of ability to see in the dark (McFarland, Dorney, Warren, & Ward, 1960). There is also a reduction in the individual's ability to react to scotomatic glare, or sudden exposure to bright light, such as a flashbulb or the headlights of an oncoming car at night (Wolf & Gardiner, 1965). Although there are only minimal data on depth perception, there appear to be reductions in stereopsis, the perception of three-dimensional space resulting from the varying input that reaches the two eyes (Bell, Wolf, & Bernholz, 1972).

7.01.8.1.2 Clinical implications

Given the centrality of vision to many activities, changes with age in the eye's basic functions can have profound psychological effects. One set of problems relates to discomfort and frustration caused by poorer acuity and reduced focusing power. Even if visual problems can be corrected with glasses or contact lenses, there are residual symptoms that may remain in special circumstances such as when the individual overworks or is trying to read small print. Older adults report experiencing as problems sensitivity to glare, difficulty seeing in dim light, and problems focusing on near objects (Kosnik, Winslow, Kline, Rasinski, & Sekuler, 1988). When these problems become more persistent, they may propel the individual toward a threshold experience.

Presbyopia, although reached after a gradual process of changes in the lens, is often perceived with relative suddenness by the individual (Carter, 1982). The immediacy of this apparent change, given the association that many people have between presbyopia and the infirmities of age, makes it more likely that the change will be negatively interpreted. The necessity of wearing bifocals adds the complication of requiring the individual to adjust to a new and awkward way of using corrective lenses.

Difficulties in depth perception and dark adaptation can heighten the older adult's vulnerability to falls (Felson et al., 1989; McMurdo & Gaskell, 1991), adding to the tendency to overaccommodate due to concerns about bone fragility and stiffness. Visual losses can increase the individual's dependence on others (Hakkinen, 1984), interfering with the older adult's ability to complete basic tasks of living such as driving, housekeeping, grocery shopping, and food preparation (Branch, Horowitz, & Carr 1989; Rudberg, Furner, Dunn, & Cassel, 1993). Apart from the practical implications, these changes can further erode the individual's physical identity.

Finally, age changes in vision can detract from the older adult's ability to enjoy leisure and esthetic activities, and even to choose appropriate clothes (Morgan, 1988). Although not a serious problem compared with difficulties in driving, such changes can be annoying and perhaps lead to derision by others. Other leisure activities involving the perception of color and fine detail may be interfered with, such as needlepoint, gardening, word puzzles, and painting. Loss of the ability to enjoy these activities add further to the threshold experience which may be crossed each time a new visual function is altered or affected by aging.

A number of changes in visual functioning can, fortunately, be compensated by corrective lenses, increases in the ambient lighting, and efforts to reduce glare and heighten contrast between light and dark. Corrective surgery for cataracts can have a number of widespread positive effects on daily life (Brenner, Curbow, Javitt, Legro, & Sommer, 1993). The success of these efforts depends on the individual's willingness to persist in trying new ideas when the old methods no longer work, a process that might be enhanced through clinical intervention. Nevertheless, a point may be reached within each sphere of functioning in which the individual's range of movement becomes compromised. Furthermore, the situation may not permit compensation, as is true for night driving. Again, clinical sensitivity plays an important role in helping the older person accommodate to this age-related change in a valued function.

7.01.8.2 Hearing

7.01.8.2.1 Age changes

Presbycusis, the general term used to refer to age-related hearing loss, actually includes several specific subtypes reflecting different changes in the auditory structures. The most common form of hearing loss reduces sensitivity to high-frequency tones earlier and more severely than sensitivity to low-frequency tones (Van-Rooij & Plomp, 1990). The loss of high-frequency pitch perception is particularly pronounced in men (Lebo & Reddell, 1972). Speech perception is affected both by the various forms of presbycusis operating at the sensory level and by changes in the central processing of auditory information at the level of the brain stem and above (Van-Rooij & Plomp, 1992). Translated into speech discrimination, this means that older adults suffering from presbycusis have greater dificulty perceiving sibilants, such as the "s" in plurals.

In addition to the effects of aging on speech discrimination due to the loss of high-pitched tone sensitivity are the effects of aging on the ability to hear when there is interference or distraction. Age effects begin to appear even as early as 40 years in the understanding of sentences under a variety of distorting conditions, particularly when the speech signal is interrupted (Bergman et al., 1976). Other conditions known to impair speech perception in the aged include higher rate of presentation, deletion of parts of the message, competition from background noise or competing messages, and reverberation (Neils, Newman, Hill, & Weiler, 1991).

7.01.8.2.2 Clinical implications

Hearing deficits interfere greatly with interpersonal communication, leading to strained relationships and greater caution by the elderly in an attempt to avoid making inappropriate responses to uncertain auditory signals. They also reduce the older person's ability to hear noises such as a siren or a door knock (Gatehouse, 1990). These changes are almost impossible to avoid noticing (Slawinski, Hartel, & Kline, 1993), and it is perhaps for this reason that hearing loss forms a threshold for a large percentage of individuals over the age of 70 years and particularly those in their 80s (Whitbourne, 1996b). There is evidence linking hearing loss to impaired physical functioning (Bess, Lichenstein, Logan, & Burger, 1989) and psychological difficulties including loneliness (Christian, Dluky, & O'Neill, 1989) and depression (Kalayam, Alexopoulos, Merrell, & Young, 1991).

Those who interact with hearing-impaired elders can benefit from learning ways to communicate that lessen the impact of age-related changes (Slawinski et al., 1993). Modulating one's tone of voice, particularly for women, so that it is not too high, and avoiding distractions or interference, can be important aids to communicating clearly with older adults. The clinician can also use observations of the elderly client's reaction to communication difficulties in therapy as the basis for clinical recommendations. For example, identity accommodation can be encouraged in a client who denies the existence of an obvious hearing deficit; a client who has no apparent hearing deficit but appears preoccupied with this particular threshold will need to develop a more balanced approach to this area of functioning.

7.01.8.3 Balance

7.01.8.3.1 Age changes

The effects of age on the vestibular organs involve the losses occurring in the sensory structures as well as in the pathways to the higher levels of the nervous system (Johnsson & Hawkins, 1972; Rosenhall & Rubin, 1973). There are also reductions in the numbers of Purkinje cells in the cerebellum (Hall, Miller, & Corsellis, 1975) which could result in lowering of reflexive abilities to adjust the body's posture to changes in position. The apparent results of these changes in the vestibular system are increased dizziness and vertigo in older adults (Toglia, 1975). Not only are these sensations unpleasant, but they can increase the likelihood of accidental falls.

However, structural changes in the vestibular system do not account entirely for the phenomena of dizziness and vertigo. There is considerable plasticity within the vestibular system so that loss of receptor cells may be compensated by the activity of structures in other sensory systems (Teasdale, Stelmach, & Breunig, 1991). For example, the positional receptors in the somesthetic system appear to be less vulnerable to aging effects (Babin & Harker, 1982). Conversely, the loss of information from more than one sensory system, such as the visual and the vestibular systems, can make it difficult for the older person to compensate successfully (Manchester, Woollacott, Zederbauer-Hylton, & Marin, 1989). Slowing of central integrative processes responsible for maintaining postural stability can also contribute to increased likelihood of falls. It may take longer for the older adult to integrate information from the vestibular, visual, and somesthetic systems, resulting in less efficient control of posture under changing body positions (Teasdale et al., 1991).

7.01.8.3.2 Clinical implications

Balance is an essential element of moving about effectively in the environment. Aging of the vestibular system brings with it the potential for the individual to feel insecure in moving, particularly under conditions that are less than ideal, such as sloping, steep, or uneven surfaces. Fear of falling due to other changes in mobility can increase the individual's anxiety and perhaps exacerbate any true deficits in vestibular functioning. Conversely, individuals who through identity assimilation ignore signs of dizziness and vertigo may place themselves in danger as they may not be able to avoid a fall when and if they do lose their balance.

There are social consequences of aging of the vestibular system as well. The older adult who experiences dizziness and vertigo may fear appearing disoriented in front of other people, perhaps due to concern about appearing intoxicated or mentally confused. A desire to avoid such embarrassment may lead the individual to avoid leaving the home, creating unnecessary limitations on social opportunities.

Nevertheless, it remains the case that vestibular dysfunction is not an inevitable consequence of the aging of the vestibular system. Furthermore, compensation is possible if the individual is able to adapt other sensory systems to make up for vestibular losses (Lord, Clark, & Webster, 1991). Such compensation seems to be more likely to occur if the individual is able to react in a balanced manner to the experience of dizziness or vertigo. The clinician can encourage the older client to benefit from the coping strategies that involve seeking other cues, such as those provided by the somesthetic system. During episodes of dizziness or vertigo, the individual can learn to pay attention to stance and bodily orientation, learning to judge the position of the lower body limbs to make better use of feedback in adjusting posture (Hu & Woollacott 1994a, 1994b; Meenwsen, Sawicki, & Stelmack, 1993).

7.01.9 CONCLUDING OBSERVATIONS

In this chapter, a number of age-related changes have been described that occur throughout the body's organ systems and sensory processes. The multiple threshold model postulates that an individual's reactions to these changes varies according to how central the area of functioning is to identity as well as according to whether the individual approaches the age change through identity assimilation or accommodation. The problems involved in using overaccommodation or overassimilation have also been described.

Clinicians can learn from this approach to pay greater attention to the subtle and not-so-subtle cues that elderly clients give regarding the concerns they have about the functioning of their bodies. Assessments of older adults in particular, but also adults in middle age, can benefit from detailed history-taking not only of "health" problems but also of the individual's appraisal of and reaction to normal age-related changes in physical and sensory functioning. Such questions are particularly important for the clinician to raise because older clients are likely to be reticent in raising delicate and potentially embarrassing concerns about how their bodies are aging. Clinicians should also be encouraged to narrow their questions as specifically as possible to particular areas of functioning rather than explore issues related to "aging" or "health" in general. Such general questions are easily disregarded, as most older individuals tend to report that they are in good health even if they have a number of specific age-related limitations (Heidrich & Ryff, 1993).

Authors in the field of clinical geropsychology have, for years, advised clinicians to examine their own age biases and attitudes toward elderly people. This admonition definitely applies with regard to the aging of the body, as clinicians who are a product of Western culture have undoubtedly acquired a number of negative attitudes toward the loss of functioning that is so generally associated with old age. Less well recognized, though, is the need for the clinician to examine his or her own personal aging thresholds. To the extent that the clinician harbors concern about how aging will affect his or her own appearance, physical mobility, or cognitive functioning, that clinician might approach in a defensive and unhelpful way an elderly client with apparent deficits in that area.

Finally, it is crucial for clinicians to recognize the independence, autonomy, and vitality of spirit seen in many elders, even those with severe losses or age-related limitations. The older adults seen in therapy are "survivors" who have managed to reach this point in life through resiliency and an indefatigible ability to adapt to change. They are coping daily with physical changes that would daunt individuals many years their junior. Therapists who condescend to the elderly or patronize them (perhaps as a result of their own fears of aging) are missing important treatment opportunities as well as important opportunities to learn from the wisdom of their clients.

7.02.1 INTRODUCTION

Understanding age-related changes, as well as stability, in highly integrated cognitive functions is of fundamental importance for the geropsychologist since memory and cognitive abilities are often focused in an assessment setting. The geropsychologist may be confronted with elderly individuals who seek help because of worries and experiences of cognitive failures, or who are referred to an assessment by family or health professionals due to impairments in memory and thinking.

A fundamental issue for an unbiased assessment of memory and other cognitive abilities is the geropsychologist's expertise in considering strengths or preserved ability as well as weaknesses or impaired ability relative to previous functioning, as well as the cognitive demands that are imposed in everyday life and how this relates to outcomes of cognitive testing. Other issues refer to the application of theoretical guidelines for analyzing performance, including the mechanisms involved, taking into account individual factors and the sociocultural context for cognitive functioning in aging.

This chapter discusses various aspects of cognitive functioning in aging in a context that is intended to correspond to that of the clinical geropsychologist, where considerations are based on detailed information about the individual in the assessment setting as well as outside the clinic. Other chapters in this volume address reasons for assessment of elderly people, including principles and methods. The present chapter provides a solid base for these more applied contributions. Given the limitation of a single chapter for discussing cognitive aspects of aging, the reader is directed to consult recent reviews for detailed information on current research on memory (e.g., Kausler, 1994), cognitive aging (e.g., Craik & Salthouse, 1992), and clinical geropsychology, including relevant chapters in the *Handbook of the psychology of aging* (Birren & Schaie, 1996 and previous editions).

This chapter is organized into subsections based on the heuristic scheme presented in Figure 1. The general idea with this scheme is that cognitive functioning must be understood and consequently analyzed within the context of noncognitive factors. The emphasis will be on aspects of memory and intellectual abilities that are likely to be addressed in an assessment setting (the term assessment is used throughout in its broadest sense and includes assessment in clinical settings as well as research approaches to various aspects of memory and cognitive aging).

The noncognitive factors depicted in Figure 1 are first discussed with reference to general aspects of memory and cognition. An overview of these domains of functioning follows, based on what is considered to be of relevance for the geropsychologist. The final section comprises an integration of cognitive aspects of aging, including messages to the geropsychologist.

7.02.2 NONCOGNITIVE INFLUENCES ON MEMORY AND COGNITION IN AGING

7.02.2.1 Types of Aging

Psychological aging is a complex interaction process involving influences from biological and social factors. In addition, the aging process is characterized by change as well as continuity and becomes manifest in a multidimensional and multidirectional manner. The former refers to the differential view on aging in which various abilities are affected differently, while the latter refers to the observation that certain abilities may deteriorate gradually, whereas still others remain stable or even improve.

The cascade metaphor of aging, proposed by Birren and Cunningham (1985), represents a heuristic simplification in the context of geropsychological assessment. The metaphor is based on the separation of primary, secondary,

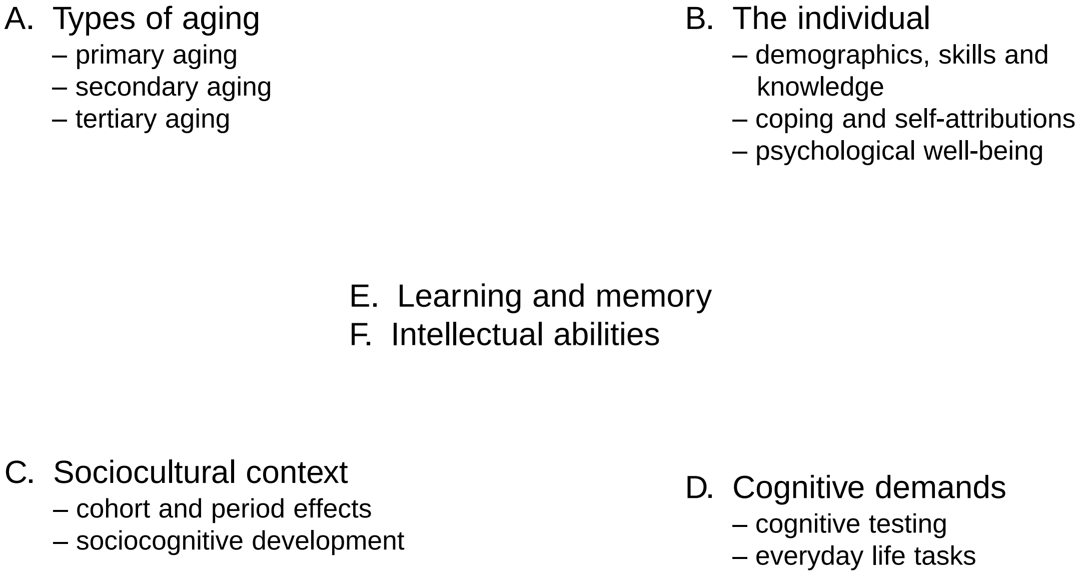

Figure 1 An analytical scheme for understanding and assessment of cognitive functioning in aging.

and tertiary aging patterns. Primary aging refers to intrinsic sources producing irreversible changes but otherwise a healthy or normal aging trajectory. Secondary aging refers to changes due to illnesses or pathology, adding to the inevitable primary aging. Tertiary aging refers to factors increasing the mortality risk and the pattern of terminal decline that becomes manifest preceding death. At the individual level this may be seen as a "curvilinear" dramatic drop while at the group level as a linear decline (cf. Berg, 1996).

It could easily be argued that it is impossible fully to separate the three theoretical aging types. However, in an assessment it is usually required that the geropsychologist concludes whether an observed impairment is to be diagnosed in terms of dysfunction or whether the impairment is to be considered within the borders of "normal aging." The phenomenon of terminal decline (e.g., Johansson & Berg, 1992) must also be taken into account, but is otherwise not an obvious diagnostic issue.

7.02.2.1.1 Primary aging

With increasing age we can expect less primary aging and more secondary and tertiary aging. Although the likelihood of sole primary aging decreases substantially with age because of increased morbidity, primary aging constitutes the bottom line for our understanding of cognitive aging.

Primary aging is, in practice, defined as the lack of illnesses that potentially could be diagnosed. In a population-based random sample of nondemented community-dwelling individuals aged 75 to 96 years, Wahlin et al. (1993) had to exclude 38% of the participants in order to meet their health criteria. Of these, 19% were excluded because of a Mini-Mental State score (MMSE) below 25 (Folstein, Folstein, & McHugh, 1975), 4% due to psychiatric disease and/or medication, and 15% due to values of serum vitamin B^{12} or thyroid-stimulating hormone indicative of disease.

Primary cognitive aging is principally characterized by a reduction in the speed at which information is processed in the cognitive system (e.g., Light, 1991; Salthouse, 1993). This slowing affects all cognitive processes where speed of behavior is an essential component, for example, in problem solving or executive functioning. In many tests, time limits are therefore more disadvantageous for an elderly person as compared to a younger individual.

A conceptual distinction within primary aging is that between usual and successful aging. According to Rowe and Kahn (1987), usual aging refers to normal aging heightened by the effects of extrinsic factors, both physical and psychosocial. In successful aging, these extrinsic influences have a neutral or positive role in maintaining functioning. As emphasized by Rowe and Kahn, the elucidation of factors that explain success is of great value for potential interventions, including preventive efforts, aiming at successful aging. Hill, Wahlin, Winblad, and Bäckman (1995) followed this route and examined the predictive strength of demographic and life-style variables for memory performance and ability to utilize cognitive support in very old age. The authors concluded that among healthy elderly persons, those who were younger, better educated, and more socially active not only improved more from cognitive support, but also demonstrated better overall performance. Further, level of exercise (in terms of walking or bicycling) was found to be a reliable predictor of episodic free recall performance. Although this was a cross-sectional study, and no conclusions can be drawn about causative relations, it was argued that the results are relevant for the selection of individuals who are likely to benefit from memory training programs. Identifying factors important for level of cognitive performance (such as level of social activity or exercise) may also have implications for other interventions.

7.02.2.1.2 Secondary aging—physical health

Secondary or disease-related aging becomes significantly more important with increasing age. It is well known that age is associated with an increased prevalence of a variety of diseases that may affect cognitive and memory functioning (e.g., Brody & Schneider, 1986; Fries & Crapo, 1981). Among persons over 65, more than 80% have at least one chronic illness, and many individuals have multiple diagnoses.

In addition to an even more pronounced slowing of speed (e.g., Salthouse, 1993), other intellectual abilites are also likely to become affected by various illnesses. A few examples are sufficient to illustrate the effects of secondary aging on cognitive abilities: the cardiovascular system is prone to age-related changes, the prevalence of heart disease among those 65 years of age and older in the Western world is estimated to be approximately 30% (Epstein et al., 1965), and the treatment of hypertension among elderly adults is considered by many geriatricians to be an almost normal and inevitable medication in aging. It has been demonstrated that cardiovascular disease has negative impacts on memory and cognition (e.g., Barclay, Weiss, Bond, & Blass, 1988; Grut, Forsell, Hill, Bäckman, & Winblad, 1995). Furthermore, the negative relation between elevated blood pressure and cognitive functioning has been documented in several longitudinal investigations (e.g, Farmer et al., 1990), and performance differences may also exist as a function of blood pressure medication (e.g., Elias, Wolf, D'Agostino, Cobb, & White, 1993). Also, older people may have health-related motor impairments that interfere with performance on psychological tests. Examples include tremor associated with Parkinson's disease, or difficulties associated with severe arthritis. Obviously, it may be necessary to modify tasks that put demands on hand motor functioning. Additional examples concern the negative relation between cognitive performance and such diverse conditions as diabetes (e.g., Bale, 1973), epilepsy (e.g., Dikman & Matthews, 1977), hyperthyroidism (Gambert, 1988), hypothyroidism (Mennemeier, Garner, & Heilman, 1993), or diseases related to vitamin deficiency (e.g., Wahlin, Hill, Winblad, & Bäckman, in press). It is well known that visual acuity (Lerman, 1983) and hearing, especially of high-frequency tones (Ordy, Brizzee, Beavers, & Medart, 1979), decline with age. In the assessment situation, it therefore becomes neccessary first to make sure that the older person has sufficient hearing or vision abilities to meet the sensory demands of the tasks at hand. It is notable that even within normal ranges, sensory functioning seems to be a strong late-life indicator of intellectual functioning (Lindenberger & Baltes, 1994).

Comprehensive health screening is rarely performed in cognitive aging studies. For the clinician, this should be kept in mind in using results from scientific reports as normative data. More recent studies of age-related effects on memory and other cognitive performance, however, have tended to screen for potentially confounded critical aspects of physical health (e.g., Bäckman & Wahlin, 1995; Hill et al., 1995; Robins Wahlin, Bäckman, Wahlin, & Winblad, 1993, 1996; Wahlin, Bäckman, & Winblad, 1995). Given the complexity of the potential impact of health-related factors, it is difficult to present clear-cut recommendations to the geropsychologist. Generally speaking, it is however important to evaluate performance, keeping in mind that influences other than what is addressed by the diagnostic question must be taken under serious consideration by the geropsychologist.

There exists at present no clear consensus about the differentiation between primary aging and pathology. This distinction becomes increasingly difficult with age, with the risk of both over- and underdiagnosis, that is, defining assessment results within the category of "normal aging" as disease/illness or ascribing an impairment to "normal aging." Also, the symptoms for many diseases change and tend to be more diffuse, in addition to prevalent comorbidity in old age (Fozard, Metter, & Brant, 1990). Furthermore, a diagnosis of disease is often accompanied by certain treatment efforts and with potential side-effects on cognitive functions. For example, Berg and Dellasega (1996), examined the relationships between cognitive function and psychotropic medication use in the H70 population-based sample in Sweden over a nine-year period (see Section 7.02.3.2.1). About one-third of the sample was on a drug regimen including anxiolytics, hypnotics, and antidepressant medications. The study showed that these psychotropics had a negative effect on most cognitive functions, although the effects generally were found to be moderate.

The dementia syndrome represents a diagnostic category of particular relevance for cognitive aging, since dementia is the single most devastating group of illnesses in which memory disturbances and cognitive impairments are cardinal outcomes. We will only address a few issues here. Dementia is extensively discussed in Chapter 10, this volume. The prevalence of dementia increases with age and the incidence rates are considerable (e.g., Fratiglioni et al., 1991; Johansson & Zarit, 1995). Dementia also demonstrates the principal difficulties in separating primary and secondary aging at an early stage, despite findings of significant impairments already present in the earliest, preclinical stage. Johansson and Zarit (1997) examined this "borderline issue" in a longitudinal study of a population-based sample of people aged 84 and older. They found that nondemented subjects who were diagnosed with "mild dysfunction" because of their performance were 11 times more likely to develop dementia within a two-year period, and seven times more likely to become demented over a four-year period. Their results also provide further evidence for terminal decline, as the likelihood for subsequent mortality was greater among individuals diagnosed with "mild dysfunction." The mortality risk was three times greater over two years and five times greater over four years compared with individuals who were rated as cognitively intact (see Figure 2).

The insidious onset of many diseases, like that of primary degenerative dementia (e.g., Alzheimer's disease) presents particular diagnostic problems. As pointed out by Sliwinski, Lipton, Buschke, and Stewart (1996), the identification of preclinical dementia is complicated by the overestimation of age effects on cognitive measures through an underestimation of the mean and an overestimation of variance. This notion becomes more important with increasing age, because of higher prevalence rates and increased likelihood of the incidence of dementia. Besides the neccessary criteria of impaired memory and other cognitive abilities, a functional criterion is generally employed for the definition of a clinically manifest dementia. This functional criterion, as in the case of the *Diagnostic and statistical manual for mental disorders* (*DSM*; American Psychiatric Association, 1987, 1994), requires that cognitive impairments need to be of sufficient severity to interfere with social or occupational functioning. A problem, however, is that cognitive demands may vary with age. The risk of underdiagnosis tends to be greater with the oldest-old due to lower cognitive demands in everyday life which makes it less likely that impairments will be uncovered. A more detailed discussion about inputs from the sociocultural context follows in Section 7.02.2.3.

7.02.2.1.3 Summary

Aging is not a unitary process but the complex outcome of numerous interactions with biological, psychological and social subprocesses. The outcome can roughly be categorized using three broad aging types: primary, secondary, and tertiary aging. The distinction between primary and secondary aging often corresponds to what is expected of the geropsychologist. A differential view of cognitive aging means that while performance in certain functions has declined and may be diagnosed as an expression of disease, for example dementia, performance in other functions may remain within the "normal aging" category or at the border of primary aging. This is especially the case when impairments are mild or changes are subtle and where there is lack of information on decline and course of change.

7.02.2.2 The Individual

Within each type of aging pattern, described above, one can discern features unique to the individual. Such individual or subject-related factors refer to exposures that have affected the individual throughout life. Whereas certain factors reflect basic demographics like age, gender, ethnicity, and socioeconomics, others refer to various aspects of personality and mental health. An understanding of the unique constellation of these influences requires the gathering of information necessary to evaluate present functioning in light of previous ability. In addition, this notion provides arguments for an interindividual difference perspective on aging.

7.02.2.2.1 Coping and self-attributions

The individual's unique repertoire of behaviors, including cognitive and emotional styles, represents another dimension to consider in an assessment. Coping and self-attributions are, in the late 1990s, more often identified as significant influences for memory and cognition. A number of coping definitions have been proposed. Most of them share the general idea
